# Chapter 1

## Introduction

Pulsating stars allow to probe the interiors of stars that is not accessible to direct observation. The physical conditions and processes within a star can only be observed through their influence on the pulsation periods and amplitudes. These are observables allowing to derive basic properties of the stars and resulted in important findings. For example, the observation of pulsation periods of Cepheids revealed a period-luminosity relation that can be used to determine distances to other galaxies. That was one of the most important findings in astronomy.

Figure 1.1 shows the diversity of pulsating stars across the Hertzsprung-Russell diagram (HRD). The dashed lines indicate the classical Cepheid instability strip, which extends to the main sequence. The stars investigated in this thesis are located at the main sequence within this extended Cepheid instability strip near  $\log T_{\text{eff}} = 3.9$  and  $\log L/L_{\odot} = 1$ , which are the  $\delta$  Sct and  $\gamma$  Dor stars. The  $\delta$  Sct -  $\gamma$  Dor hybrid pulsators are not drawn in this diagram, because their instability domain was previously not explored and they comprise a fairly new class of pulsators.

This thesis investigates this very special group of pulsating stars, which shows low frequency pulsation like the  $\gamma$  Dor stars and high frequency pulsation like the  $\delta$  Sct stars. Due to the fact that these stars show two types of pulsation they are termed  $\delta$  Sct -  $\gamma$  Dor hybrid stars or hereafter simply hybrids. There are other types of hybrid pulsators, like the SPB -  $\beta$  Cep stars, which are the more massive cousins of the  $\delta$  Sct -  $\gamma$  Dor hybrid stars. Because of the presence of two types of pulsation modes hybrid stars carry valuable information on their interior structure. The deep interiors is probed by the  $g$  modes while the outer layers are probed by the  $p$  modes. In this thesis the focus was put on the  $\delta$  Sct -  $\gamma$  Dor hybrid, the existence of this group was predicted by Dupret et al. (2004) and the first unambiguous detection discovered by ground based observations was reported by Henry & Fekel (2005).

I aim to answer the following questions: Do hybrids really exist or can their low frequencies be explained by other reasons than  $g$  mode pulsation?

**Figure 1.1:** Various classes of pulsating stars across the Hertzsprung-Russell diagram. The dashed lines indicate the classical Cepheid instability strip, which is extended to the main sequence. This is the location of the stars investigated in this thesis. Figure credit: J. Christensen-Dalsgaard, website: [http://astro.phys.au.dk/jcd/HELAS/puls\\_HR/](http://astro.phys.au.dk/jcd/HELAS/puls_HR/).

This question deserves a thorough examination of their frequency spectrum since stellar rotation, binary effects, combination frequencies, or instrumental effects present in the time series can easily mimic  $g$  modes. If there are in fact hybrid stars, what is their instability domain? Is the occurrence of hybrids in the HRD confined to the overlapping region of the  $\gamma$  Dor and  $\delta$  Sct instability strips? Space based data allow investigation of sub-millimagnitude oscillations and are well-suited for exploring this question. HD 8801 is the first firm detection of a single Am star, pulsating with  $p$  and  $g$  modes. Am stars are usually found in binary systems with slow to moderate projected rotational velocities ( $v \sin i$ ). Detailed abundance analyses of these stars were lacking before this thesis. Which inferences can be drawn from their fundamental parameters? Are they giants, evolved stars or are they subdwarfs? Classification spectra allow to discern the luminosity classes of these stars.

In order to answer these questions, high-accuracy light curves are essential. The CoRoT long runs provide such light curves and have both sufficient time sampling (8.53 minutes) and long time base ( $\approx 150$  days), in order to unambiguously identify and resolve close frequencies. Moreover, data of high sampling from CoRoT and MOST are available for investigating also the high frequency regime inaccessible with the 8.53 minute sampling. Accurate temperatures and luminosities are of fundamental importance for placing the hybrid stars in the HRD and to explore their instability domain. Thus, the photometric data are complemented by classification spectra using a multi-object spectrograph with the same settings for all of the stars. High resolution spectroscopy allows to determine the chemical abundances for bright stars and to investigate potential common features.

Since the instability domains of  $\gamma$  Dor and  $\delta$  Sct stars overlap in the HRD, the existence of hybrid pulsators may appear obvious. However, subsurface convection plays a major role within the mass range of these groups of pulsating stars damping or driving different types of oscillations ( $p$  modes and  $g$  modes). The treatment of convection is crucial for both types of pulsators for the theoretical understanding of these stars. On the red edge of the  $\delta$  Sct instability strip (IS) the convection zone stabilises pulsation, whereas for  $\gamma$  Dor a convective flux blocking mechanism is likely to drive their high-order  $g$  mode pulsation. While solar-like pulsators are well understood, the situation for  $\delta$  Sct and  $\gamma$  Dor is much more complicated.

For the first time we analysed a large sample of stars observed under the same conditions with the same instruments and the same data reduction methods with unprecedented photometric quality. Not only the photometry of CoRoT was used, but also the AAOmega classification spectra were used to derive the fundamental parameters. Hence, this work comprises a self-consistent analysis of homogeneous data sets. It is possible to study not only the modes with the maximum amplitudes but also to find  $\gamma$  Dor,  $\delta$  Sct or hybrids pulsating with sub-millimagnitude variability.

Ground-based photometric time series suffer not only from the day/night cycle that can only be alleviated by multi-site campaigns but also from atmospheric effects like bad weather, unstable atmospheric conditions (turbulence), varying extinction, and the like. These effects lead to inconvenient gaps in the data, which complicate the frequency analysis of the photometry severely and hamper the detection of low-amplitude oscillations. Space based photometry provides not only nearly uninterrupted time series but also much lower noise by circumventing the Earth's atmosphere. The improvement of the data quality becomes obvious when one considers the sizes of the primary mirrors of MOST or CoRoT being only 15-cm and 27-cm, respectively.

This thesis was part of a project, which investigated the  $\delta$  Sct IS. Naturally, a close cooperation with A. Kaiser (PhD student) and W. W. Weiss was established. The subject of A. Kaiser's thesis was the investigation of the connection of metallicity and pulsation near the cool border of the  $\delta$  Sct IS. Both theses (mine and A. Kaiser's) need fundamental parameters of the program stars. A. Kaiser employed a Bayesian approach and different model atmospheres while my work used a frequentist approach. All of the fundamental parameter determination is my original work.

## 1.1 Nonradial Stellar Pulsation

Pulsation is called radial pulsation, when the star is expanding and contracting in radius periodically. Classical Cepheids or RR Lyrae stars are examples for radial pulsators. Not only do they change their radius but also their effective temperature (i.e. colour), which is negligible for low-amplitude pulsators, as are the stars investigated in this thesis. Due to the pulsation the star brightens and dims periodically.

Within the extended Cepheid instability strip towards the main sequence,  $\delta$  Sct stars show such pulsations but do also show nonradial pulsation. That is, the pulsation has not only radial components but also nonradial components. Such pulsations are described by spherical harmonics, which are characterised by three quantum numbers usually denoted  $n$ ,  $\ell$ , and  $m$ . The radial order is denoted by  $n$ , the spherical degree by  $\ell$ . This number counts the total of node lines across the surface and finally  $m$ , which is the azimuthal order counting the node lines that cross the equator. The basic assumption of applying the spherical harmonics is that the stars is spherically symmetric in its equilibrium. Radial modes have no node lines on the surface, thus, their  $\ell = 0$ , while  $\ell \neq 0$  for nonradial modes.  $m \in \{-\ell, \dots, \ell\}$  if node lines cross the equator of the star, where prograde modes (modes that move in the same direction as the stellar rotation) have positive signs and retrograde modes are indicated by negative signs.

High order modes are modes that show many nodes across a line from

the surface to the centre i.e.  $n$  has a high value. These modes are within the so called asymptotic regime, where the periods or frequencies show constant spacings (Tassoul 1980). Low degree modes or  $\ell$  being a low number show a few nodal lines across the surface. Such modes are commonly detected in  $\delta$  Sct and  $\gamma$  Dor stars or other pulsators.

Pulsation modes can have  $p$  mode character, that is, they are sound waves propagating through the star. The restoring force is the pressure, hence the term  $p$  modes. The gas motion is primarily vertical, where as for  $g$  modes it is horizontal. The restoring force is the buoyancy, which is linked to gravity, hence the term  $g$  modes. These modes are consistently nonradial and therefore their  $\ell \geq 1$ . A detailed introduction to stellar pulsation can be found in Aerts et al. (2010). Some theoreticians use the the convention of negative values for  $n$  and/or the radial order is termed  $k$  to avoid confusion with  $p$  modes.

Examples of  $p$  mode pulsators are the groups of stars in Fig. 1.1 represented by the hatched ellipses with negative slopes of the lines, and examples of  $g$  mode pulsators are indicated by the hatched ellipses with positive slopes.

## 1.2 $\gamma$ Dor stars

The photometric variability of  $\gamma$  Dor is known since the 1960's. It was for a long time not clear whether its variability is due to a spotted surface and hence the period reflects the rotation period or the star is pulsating. In the 90's it became more and more clear that there is a new class of pulsating stars close to the red edge of the  $\delta$  Sct instability strip. A new class of nonradially pulsating stars was already anticipated by Krisciunas (1993) and Balona et al. (1994). This new class of variables, the  $\gamma$  Dor stars named after its brightest and longest known member, was finally defined by Kaye et al. (1999).

“ $\gamma$  Dor stars are pulsating intermediate-mass stars that are located at the cool border of the  $\delta$  Sct IS in the HRD. Their masses range typically from 1.5 to 1.8  $M_{\odot}$  for solar metallicity. They pulsate in high-order  $g$  modes contrary to  $\delta$  Sct stars that pulsate in low-order  $p$  modes with higher frequencies. In the narrow region in the HRD where  $\gamma$  Dor stars are found, the convective zones associated with the partial He and H ionisation begin to merge and form a single convective envelope. The exact extension of the convective envelope is uncertain and depends on the treatment of convection”. (from Dupret et al. 2007). Nonetheless, the extension of the convective envelope is of crucial importance to the understanding of the driving of  $g$  modes.

Since the discovery of the photometric variability of  $\gamma$  Dor by Cousins (1960) forty years passed until a first explanation for the low-frequency pulsation of  $\gamma$  Dor stars could be given by Guzik et al. (2000). For a long time it was believed that the variability of early F-type stars was due to a spotted surface since the  $\kappa$ -mechanism cannot excite high-order  $g$  modes. Although

**Figure 1.2:** Figure 1 from Dupret et al. (2007) shows the evolution of the convective core for  $\gamma$  Dor stars (left panel) and the evolution of the period spacing (right panel). Figure reproduced with the permission of the publisher of CoAST.

Guzik et al. (2000) used the Frozen Convection (FC) approximation, which means no interaction between convection and pulsation, and a high metallicity ( $Z = 0.03$ ), they were able to show that a flux blocking mechanism at the base of the convective envelope can drive  $g$  modes. If the thermal relaxation time is of the order of the pulsation period, the convection zone cannot immediately react to flux changes from deeper layers. Hence, the energy is transformed to mechanical work driving low-frequency  $g$  modes. Dupret et al. (2004) used a more realistic treatment of convection, the Time-Dependent Convection (TDC) approach. They showed that the TDC did not affect significantly the driving of  $g$  modes at the base of the convective envelope. Thus they were able to support the flux blocking mechanism suggested by Guzik et al. (2000) as explanation for the observed pulsation.

The evolution of the convective core depends on the mass of the star. For lower masses the convective core grows and therefore leaves a discontinuity of the chemical composition. “In the two cases of a shrinking and growing convective core, the determination of its exact extension is subject to large uncertainties [...]. There is for example the well known overshooting parameter widely used in stellar evolution codes and which just reflects our lack of knowledge at this level” (from Dupret et al. 2007). The overshooting parameter is commonly referred to as  $\alpha_{OV}$  and this convention was followed in this thesis. The left panel of Fig. 1.2 shows the core mass as a function of evolution (core H abundance) for different initial masses. This figure is taken from Dupret et al. (2007).

Herein rests the promising diagnostic capability of gravity modes. That is, they penetrate deep layers of the star and carry information on the conditions

close to the convective core and are sensitive to chemical gradients, which influence their periods (Fig 1.2). Solar like stars or pure  $\delta$  Sct stars damp their  $g$  modes toward the surface, hence this deep insight is not possible for such stars. Thus,  $\gamma$  Dor stars are a unique test-bench for theory.

Since  $\gamma$  Dor stars pulsate in high-order  $g$  modes implying that the asymptotic theory (Tassoul 1980) applies and constant period spacings of consecutive radial orders can be expected. A. Miglio calculated frequency spacings for  $\gamma$  Dor models (Miglio et al. 2008) and could show that the spacing is sensitive to chemical gradients deep inside the star. It is expected that a young star at the beginning of its hydrogen burning phase exhibits a uniform spacing for consecutive radial orders, whereas the more the star evolves the steeper the chemical gradient becomes and the period spacing deviates from an uniform one to a more complex pattern. In fact, the period spacing becomes itself periodical with the radial order  $n$ . In this work this theoretical prediction shall be investigated.

### 1.3 $\delta$ Sct stars

The best studied group among the mentioned three classes are the  $\delta$  Sct stars. They pulsate in low-order  $p$  modes with typical frequencies of the order of 5 to 50  $\text{d}^{-1}$ . These numbers are no strict limits, and pulsations of such stars were discovered beyond these limits. Because of the low mean density, evolved  $\delta$  Sct stars have pulsation frequencies near the lower limit. However, the situation is more complex as for pure radial pulsators since  $\delta$  Sct stars have also nonradial and occasionally low-order  $g$  modes or mixed modes excited (see e.g., Breger et al. 2005). Among the  $\delta$  Sct stars, there are stars that pulsate mainly in radial modes with high amplitudes, therefore the acronym HADS (High Amplitudes  $\delta$  Sct stars) was given to that subgroup.  $\delta$  Sct stars pulsating in both radial and nonradial modes with generally low amplitudes ( $< 0.03$  mag) are thus named LADS (Low Amplitude  $\delta$  Sct stars). One of the major differences between those two groups is the  $v \sin i$ , where the HADS show the lower rotation velocities. In this thesis the term  $\delta$  Sct applies to the whole group, no differentiation is done between HADS and LADS. A comprehensive review of  $\delta$  Sct and related stars can be found in Breger (2000).  $\delta$  Sct stars often show rich pulsation spectra including combination frequencies. For example, more than 75 pulsation frequencies were reported in FG Vir by Breger et al. (2005).

In spite of the detailed studies of these stars, there are still open questions. The  $\delta$  Sct stars do not pulsate in the asymptotic regime, which complicates the interpretation of their pulsation modes. Spectroscopic mode identification is only feasible for bright stars. Without this identification the constraints on the models are not tight enough. Additionally, stellar rotation complicates

the frequency spectrum and the rotational splitting becomes complex for fast rotating stars. The global metallicity is a priori unknown and cannot be observed easily since abundance analyses only reveals the photospheric abundances. The convective overshooting of the core mixes more hydrogen into it, which prolongs the main sequence life time of the star. For a discussion of the asteroseismology I refer to Guzik (1998).

## 1.4 $\delta$ Sct - $\gamma$ Dor hybrid stars

The instability strip of  $\delta$  Sct stars overlap with that of the  $\gamma$  Dor stars, hence it is natural to look for hybrids. The group of hybrid stars is a hybrid form of  $\delta$  Sct stars and  $\gamma$  Dor stars. This means that a single star shows the pulsation behaviour of both groups - low-order low-degree  $p$  modes and high-order low-degree  $g$  modes. It should be mentioned that further types of hybrids exist (or are suspected), such as  $\delta$  Sct - solar like stars, SPB- $\beta$  Cep stars, and others. Those stars are however not subject of the present work and if the term hybrid is used in this work without more explanation,  $\delta$  Sct -  $\gamma$  Dor hybrid should be understood. A dedicated survey yielded one hybrid candidate, which is a binary in an eccentric orbit. The  $g$  modes of this star are likely tidally induced (Handler & Shobbrook 2002). In 2005 the first single hybrid was discovered using ground based data (Henry & Fekel 2005). This star is an Am star that means it belongs to a special group of chemically peculiar stars. Thus, the question should be addressed in this work if this type of chemical peculiarity is common to all hybrid pulsating stars. There are practically no detailed abundance analyses of these stars yet. Shortly before the space missions a few further detections were announced (e.g. Poretti et al. 2005; King et al. 2006; Rowe et al. 2006a; Uytterhoeven et al. 2008).

Fig. 1.3 shows typical light curves and their Discrete Fourier Transformations (DFT). The  $\gamma$  Dor stars show pulsation in the low-frequency regime, while the  $\delta$  Sct stars pulsate with higher frequencies and the hybrids show both types of frequencies.

Since  $g$  mode pulsators carry information on deep layers in stars and  $p$  modes probe the outer layers of a star, hybrids are promising targets for asteroseismology. Important information is coded in the deviations of the observed from the calculated frequencies. This code is still an enigma. Unfortunately, the theory of  $\gamma$  Dor pulsation is not yet developed as much as that of  $\delta$  Sct pulsation. Unlike the frequencies of  $\delta$  Sct stars, the frequencies of  $\gamma$  Dor stars are not well understood and no relation of frequency vs. density, temperature,  $v \sin i$  or other parameters have been found up to now.

The detection of  $g$  modes was difficult from ground based observations because of their long periods and instrumental effects. Uninterrupted space based data facilitate their detection but also may reveal other effects like stel-

**Figure 1.3:** Parts of three CoRoT LRA01 light curves (left panels) and their Fourier transformations (right panels). Top panels:  $\gamma$  Dor star, middle panels:  $\delta$  Sct star and bottom panels: hybrid.

lar rotation periods due to spots, binary effects, stellar activity, combination frequencies and other effects which mimic  $g$  modes. Thus, existence of  $g$  modes of  $\delta$  Sct stars (which means the existence of hybrid stars) can be disputed. Therefore it is important to carry out a thorough frequency analysis to exclude such effects. With the high quality space data of CoRoT this goal can be achieved and firm positive detections can be established.

Breger & Beichbuchner (1996) investigated reports of low frequency variations of  $\delta$  Sct stars by various authors. They raised the question: " $\gamma$  Dor and  $\delta$  Sct stars: Cousins or Twins?" but could not draw definite conclusions. Are they twins because of their close location in the HRD or are they cousins because of their different pulsation behaviour. In the latter case, sub-surface convection is obviously the decisive criterion because it is the most important difference. The convection – pulsation interaction is a current field of research and this thesis aims to deliver a contribution from high-quality observation of both individual stars and a statistically significant sample of stars.

# Chapter 2

## Instruments and Data Reduction

The data used for this investigation are of two different kinds: i) photometric time series from space (CoRoT and MOST) and ii) spectroscopic data from ground based observatories. The photometric time series obtained during the CoRoT Long Run a01 (LRa01, “a” indicates the anti-centre direction) are used for investigating the pulsational behaviour of the sample stars. The Julian Date (JD) of CoRoT observations is reduced to  $JD_C = JD - 2451545$  (i.e. January 1st, 2000) for practical reasons. The MOST Science Team uses the same convention and thus MOST JDs are in the same reference frame as CoRoT JDs.

From the light curves alone the pulsation frequencies can be derived with high accuracy, but complementary spectroscopy or at least narrow-band photometric indices are necessary to exploit the full potential of the data. AAOmega classification spectra are available only for a subset of the CoRoT targets, which were provided by E. Guenther (private communication) and are used to derive the fundamental parameters of the stars.

Since the first reported hybrid star, HD 8801 (Henry & Fekel 2005), and two hybrids discovered by MOST: HD 114839 (King et al. 2006) and BD +18 4914 (Rowe et al. 2006b), which are Am or suspected Am stars, high-resolution spectroscopy was obtained for the two MOST stars to analyse their elemental abundances. These high-resolution spectra were obtained with the spectrographs SOPHIE (OHP) and HARPS (ESO, La Silla).

### 2.1 Photometry

#### 2.1.1 CoRoT Photometry

The CoRoT (Convection, Rotation and Transits, Baglin et al. 2006) space telescope was launched December 27th, 2006 into a polar Low Earth Orbit (LEO). It carries a 27-cm telescope where the prime mirror is in an oblique position to avoid aperture obstruction by the secondary mirror. The CoRoT

project is led by France with the participation of other European countries including Austria. The observing strategy of CoRoT was designed to detect transiting planets by monitoring a large number of stars continuously for up to 180 days. Long time base observations are not only valuable when looking for planet transits but especially for studying pulsating stars with a complex frequency pattern. The frequency resolution of long run data is considerably higher than that for MOST targets. For stars like FG Vir (Breger et al. 2005) ground-based observations yielded an even better frequency resolution, but only few targets can be observed.

CoRoT has four CCD detectors of which two are dedicated for astero-seismology (Seismo field) and the other two are used to detect planet transit candidates (Exo field). The light curve of one star (HD 49862), analysed in this thesis, shows a long-term trend, which is also observed in other Seismo targets. The light curve was divided into three parts, where the trend of the first and the last part was almost linear and thus removed using a linear fit. The trend of the middle part was more complicated and it was removed by a quadratic fit. To avoid discontinuities the average value of each part was adjusted to the average of the whole data set. Since the total amount of data points was  $\approx 360000$  the light curve was rebinned to 4 minute sampling in order to reduce the computing time. After the binning and outlier clipping 49279 data points were retained. To avoid undesired effects of the binning on the data, the discrete Fourier transform (DFT) of the unbinned data was compared to that of the binned data and no significant difference was found.

The light curve sampling of targets in the Seismo field is 32 seconds, whereas the default sampling of the Exo field targets is 512 seconds. The latter light curves can be resampled to 32 seconds if a transit candidate is detected. If light curves of my sample were affected by such resampling then I binned the light curves back to 512 s sampling in order to guarantee the same treatment of the data.

The performance of CoRoT in space is described in detail by Auvergne et al. (2009). The space-based data from CoRoT are provided by the CoRoT team as so called N2 (Niveau 2) data. The raw data are called N1 data, which are not distributed to the scientists. The CoRoT data reduction pipeline performs all necessary reduction steps, like background correction and finally fills gaps due to the South Atlantic anomaly (SAA) by linear interpolation to avoid severe aliasing in the Fourier domain. After the data reduction by the CoRoT team there are still light curves that contain instrumental artefacts. Most notably, there are jumps in the mean level of the time series when a new warm pixel appears (see Auvergne et al. 2009).

Therefore a destepping algorithm was developed in cooperation with A. Kaiser, who implemented it in an IDL program. This destepping algorithm employs a moving two-sample t-test that detects significantly different mean values of the two samples. The number of data points contained in each bin

for which the t-test is performed, is by default 50 data points for the light curves sampled with 512 s. The bin size should be adjusted according to the stellar pulsation periods to avoid mistaking flux variations due to pulsation for discontinuities. For the Exo light curves of  $\gamma$  Dor stars the bin size was set to 30 data points.

Additionally, outlier clipping algorithms that employ running medians and running averages were used. For stars that pulsate with high amplitudes compared to the noise, like  $\gamma$  Dor stars do in several cases, the outlier clipping deserves a closer look because the pulsation signal is often strong compared to the noise. The light curve rises or declines earlier than the corresponding running average, which leads to the fact that some of the unperturbed data points meet the rejection criterion ( $3\sigma$ ) and are clipped. To avoid this undesired effect, running medians and running averages were combined and the box size of the running averages were set to 30 data points for the Exo data.

The N2 light curve of a star from the CoRoT archive is shown in Fig. 2.1 (top light curve), where all data points were included. The result of our desteping algorithm (bottom light curve) is shown for comparison. Figure 2.2 shows the corresponding DFT spectra. It would require careful correction for jumps and trends of all light curves to get rid of any residual steps and trends that are still present in the final light curves, but this is not feasible for a large amount of light curves within a reasonable time. As a result a slightly increased noise compared to perfectly reduced data was accepted. This slightly higher noise does not affect the basic scientific results and the data are still of excellent quality. An awkward problem is posed by cosmic particle hits causing warm pixels, whose charge then decays exponentially to the normal value (see Auvergne et al. 2009). Since the time scales and amplitudes of such events are very different and the correction for such cases would require fits with individual parameters for each jump and each star, I abstained from fitting exponential functions. Rather, the average of the part affected by the exponential decay was adjusted to the average of the whole time series. This allows for fast data reduction of a large sample at the cost of low-frequency instrumental signal below  $0.5 \text{ d}^{-1}$ .

An example for a cosmic hit and exponential decay can be seen in the figure at  $\text{JD}_C \approx 2870$  where the jump could be corrected by a linear fit. This is not always possible (see glitch at  $\text{JD}_C 2940$ ) and the resulting light curves retain artefacts. These artefacts cause low-frequency peaks in the Fourier transform (Fig. 2.2, frequencies  $< 0.75 \text{ d}^{-1}$ ), but do not prevent the detection of  $g$  modes of  $\gamma$  Dor type since their frequencies and/or amplitudes are higher than those caused by residual artefacts.

The CoRoT LRA01 contains 11403 light curves in the Exo-field. All these light curves were treated as described above and their Fourier transforms were calculated. The resulting light curves and Fourier transforms were visually inspected and kept, if they showed signal either in the  $\gamma$  Dor or both the  $\gamma$  Dor

**Figure 2.1:** CoRoT N2 data as provided by the CoRoT team (black open circles, all data points including flagged ones). The red dots are the data after detrending and destepping offset by -50000 counts for better visibility. These data were used for further investigations.

and  $\delta$  Sct regime. Eclipsing binaries were rejected if there was no obvious pulsation signal. In this way 418  $\gamma$  Dor candidates and 274  $\delta$  Sct -  $\gamma$  Dor hybrid candidates were identified. For these stars the data reduction pipeline with tuned parameters was reapplied to better remove jumps and outliers. Finally the resulting light curves were analysed using the frequency analysis tool SigSpec (Reegen 2007), which is described in Chap 6.  $\gamma$  Dor stars are not distinguishable from SPB stars based on the light curve alone implying misclassified SPB stars among the 418  $\gamma$  Dor candidates. For the final analysis only those stars were investigated for which AAOmega spectra are available (either of the 2008 or 2009 run).

The automated supervised classification of Debosscher et al. (2009) was not used, because of ambiguities and the risk of misclassifications. Only two stars were identified in the COROT LRA01 by this tool as  $\gamma$  Dor but 435 as SPB because of the indistinguishable light curves. The numbers of the SPB stars of this automated tool is in fair agreement with the number of candidate  $\gamma$  Dor stars (including SPB) that I obtained.

Since CoRoT has a broadband filter that is sensitive to wavelengths up to 8000 Å the amplitudes are not comparable to published amplitudes of other stars observed in the Johnson UBV system.

**Figure 2.2:** CoRoT N2 data only corrected for outliers (black) compared to further data treatment (red). Residual artefacts have less severe effects than in the original N2 data only corrected for outliers. The signal between 1 and 3 c/d is due to stellar pulsation. The red Fourier transform is shifted by -100 counts for better visibility.

### 2.1.2 MOST Data

In June 2003 the Canadian microsatellite MOST (MicroOscillations and STellar variability) was launched, carrying a 15-cm telescope. The mission is described in full detail in Walker et al. (2003). It was dedicated to detect solar like oscillations in close-by main sequence stars. This goal turned out to be too optimistic, however, the scientific value of MOST was largely enhanced by its capability to observe stars without interruption up to 6 weeks retaining a high quality of the data. MOST exceeded by far its anticipated life-time and is now at the time of writing entering its ninth year of operation. The data quality by that time was unprecedented and new discoveries were made. Two discoveries are of importance for this work: both, HD 114839 (King et al. 2006) and BD +18 4914 (Rowe et al. 2006b) are hybrid stars, sufficiently bright for follow-up spectroscopy.

The MOST data cover about one month of uninterrupted photometry. Four stars observed by MOST are analysed in this thesis: HD 114839, BD +18 4914, HD 73449, and HD 73854. The former two stars were suspected to show Am characteristics, while the latter two stars were observed in the Praesepe cluster. MOST can observe stars in three observing modes: a) Fabry-mode: where the entrance pupil is projected through a tiny Fabry lens onto the CCD detector. The purpose of the lens is to minimize the effect of the satellite jitter on

the data. Due to the dispersion of the stellar light onto a doughnut-shaped area only bright target stars yield enough signal to noise per pixel. A detailed description of this mode and the data reduction can be found in Reegen et al. (2006). b) Direct Imaging mode: The image of the star is directly projected onto the CCD-sensor without a Fabry lens. A subraster of typically 20x20 pixels is read out and is available as image. The data reduction for this observing mode is described in Rowe et al. (2006a) and Huber & Reegen (2008). c) Guide star mode: No image data but intensities and integration times of each individual guide star are recorded.

Before June 2006 two separate CCDs were used, where the Science CCD has better characteristics and recorded Fabry and DI targets, while the tracking CCD was used by the attitude control system and recorded the intensities of the guide stars. A charged particle hit knocked out the tracking CCD in June 2006, and the Science CCD had to be used for the attitude control. Since then a star can be observed as a direct imaging target and a guide star simultaneously. Due to download limitations only 4 to 5 direct imaging targets can be selected, but the number of observable guide stars is much higher (up to  $\approx 70$  simultaneously). Consequently, the majority of MOST targets were observed in the guide star mode. A description of the guide star data and the corresponding reduction pipeline can be found in Hareter et al. (2008). Due to the lack of background information the data reduction relies on nonvariable comparison stars to reduce the stray light effect.

The basic characteristics of MOST data are short time sampling on the order of 1 to 30 seconds (depending on the brightness of the primary science target) and almost uninterrupted time series up to 6 weeks. Unfortunately, MOST photometry suffers from stray light due to the bright earth that makes further data processing necessary. The main goal of the data reduction pipelines was to retain as many data points as possible. Simply removing all stray-light affected data points would result in a high loss of data leading to a bad spectral window. It is not possible to remove all orbital artefacts with no undesired side effects on potential stellar pulsation signal, thus the orbit frequency and its harmonics are still present after the data reduction. The amplitudes of these orbit artefacts are, nonetheless, drastically reduced to an acceptable level. This implies that frequencies due to stellar pulsation which are close to  $14.2 \text{ d}^{-1}$ ,  $28.4 \text{ d}^{-1}$ , and so forth are not reliably detectable unless they exhibit huge amplitudes and a favourable phases.

The MOST data analysed in this thesis are light curves of HD 114839, BD +18 4914, HD 73449 and HD 73854. The latter two are members of the Praesepe cluster. BD +18 4914 was observed 5 times (2004 - 2008), mainly as direct imaging target while HD 114839 was observed only once in 2005 as a guide star. These two discoveries were published by Rowe et al. (2006b) and King et al. (2006), but for BD +18 4914 no further analyses of the MOST data were published yet. Fig. 2.3 shows the raw data extracted from the archive

files, where outliers were already removed ( $3\sigma$  clipping). The reduced data are overplotted for comparison. The decorrelation technique based on presumably nonvariable stars works well and reduces the strong artefact at the MOST orbit frequency and its harmonics drastically without introducing spurious peaks (lower panel). The small peaks near the MOST artefacts are stellar pulsation signal.

The amplitudes of MOST photometry should be taken with care, since, like for CoRoT, a custom broadband filter was applied that cuts off at  $\approx 400$  nm bluewards and  $\approx 700$  nm in the red, thus amplitudes cannot be easily compared to published amplitudes that were determined in the standard Johnson or Strömberg filter systems. Moreover, the decorrelation technique can reduce amplitudes as shown by Reegen et al. (2006).

Since  $\gamma$  Dor stars pulsate in the asymptotic regime, they are supposed to exhibit regular period spacings of modes of equal spherical degree  $\ell$ . Since the expected period spacings from theory (Dupret et al. 2007; Miglio et al. 2008) are of the order of one hour, a sufficient time base is required to resolve such period spacings. The period error depends on the length of the data set, which means that a minimum observing time is required. Figure 2.4 shows the period uncertainties of data set lengths typical for MOST (32 days of Praesepe 2008 and 48 days as maximum) and CoRoT (131 days of LRa01). The frequency uncertainty was assumed conservatively to be  $1/T$ , where  $T$  is the data set length in days. This plot shows that it is possible to detect expected period spacings of  $\gamma$  Dor for  $\ell = 1$  or  $2$  with time bases of MOST data, if the periods themselves are short enough. The situation of course is much better for CoRoT LRa01 data. The dash dotted blue lines indicate the regime of the expected period spacings that were taken from Miglio et al. (2008). As the exact values of the period spacings depend on the physical properties of the stars, the vertical lines give an estimation rather than to show exact values.

**Figure 2.3:** Raw data compared to reduced data of MOST. The upper panel shows the extracted light curve from the archive files, where outliers are already removed. The red dots represent the reduced data. Lower panel: the adjacent DFT (black: raw data, red: reduced data). The dotted vertical lines indicate the MOST orbit frequency and its harmonic and  $1 \text{ d}^{-1}$  sidelobes.

**Figure 2.4:** Period errors as a function of period for MOST (timebase 32 and 48 d, red full line and orange full line, respectively) and CoRoT LRA01 data (131 d, black full line). Expected average period spacings of a  $1.6 M_{\odot}$  model on the ZAMS are plotted as horizontal dash-dotted lines for  $\ell = 1, 2$  and  $3$ .

## 2.2 Spectroscopy

### 2.2.1 AAOmega Classification Spectra

Two sets of AAOmega classification spectra are available. The first set was taken in 2008 covering stars of the Initial Run (IR) and the LRA01. In 2009 a second set of the same sky region was obtained. The spectra were taken and reduced by E. Guenther. The AAOmega instrument is mounted on the Anglo-Australian Telescope (AAT) at the Anglo-Australian Observatory (AAO). This instrument is a multi-fibre spectrograph that can observe up to 392 objects simultaneously. The instrument has a dichroic beam splitter that feeds a blue and a red arm. The wavelength range is from  $\approx 3700\text{\AA}$  to  $\approx 8800\text{\AA}$ . The instrument is described in Sharp et al. (2006).

The resolution of the spectrograph for the multi-object mode can be between 1000 and 8000, where in my case the resolution was about 1400, and the spectra cover a wavelength region of  $\approx 3730$  to  $\approx 7430\text{\AA}$  in 2008 and  $\approx 3730$  to  $\approx 8850\text{\AA}$  in 2009. 4092 spectra are available from the 2008 run with one spectrum per star. From the 2009 run 1660 spectra are available, where 214 stars were observed twice thus 1446 stars were observed. 631 objects were observed in both runs (2008 and 2009) and 815 were only observed in 2009. The total amount of stars observed is therefore 4907 (4092 in 2008 and 815 in 2009).

Unfortunately, some spectra are affected by fringing, which may be due to damaged fibres (Sharp et al. 2006). Such spectra were excluded from the parameter determination since the hydrogen lines are distorted. Nevertheless, a hot star can be distinguished from a cool one by visual inspection or by determining the ratio of the line depth of the Ca K line compared to the  $H_\epsilon$  line. This means a  $\gamma$  Dor can be separated from a SPB star by looking at the K line.

Figure 2.5 shows two classification spectra from the 2008 and 2009 run, respectively. Two spectra of one  $\gamma$  Dor star (CID 102608070) are shown. The instrument setup was different for those two runs, hence the spectra show different count rates in the blue and red arm that explains the discontinuity in the 2009 data. The spectral resolution, however, is the same in 2008 and 2009. My parameter determination pipeline works in both cases because only a few hundred  $\text{\AA}$  centred on the hydrogen lines are used by the fitting procedure. Note, that the wavelength scale is not the same due to the fact that the 2009 spectra reach into the infrared until  $\approx 8000\text{\AA}$ .

### 2.2.2 SOPHIE and HARPS Spectra

Abundance analysis requires high resolution spectra for fitting the metallic line profiles. Therefore, a proposal entitled "Spectroscopy of Gamma Do-

**Figure 2.5:** AAOmega classification spectra from 2008 (upper panel) and from 2009 (lower panel).

radius, Delta Scuti and Hybrid Stars Discovered by MOST” was made to the Observatoire de Haute Provence (OHP), of which I was the principal investigator (PI), to obtain spectra for 8 targets. Of the two requested nights one night equivalent was awarded and four stars in total were observed in service mode.

The spectrograph of OHP is named SOPHIE, which is a cross-dispersed echelle spectrograph mounted on the 1.93-m telescope. The spectrograph provides a resolution of  $R = 40000$  in High Efficiency mode (HE) sufficient for abundance analysis and yields a signal to noise of 100 for stars at about 9th magnitude of half an hour exposure. The spectra cover a wavelength range from 3872 to 6944 Å in 39 echelle orders. The spectrograph also offers a High Resolution mode with a spectral resolution of 75000. For my project, the HE mode was preferable to the HR mode because of the low magnitudes of the target stars.

The spectrograph uses two fibres (termed A and B), where the fibre A is usually used to observe the target, while the fibre B can be used for simultaneous observation of the sky or a calibration lamp. The spectra are reduced automatically, where the optimal order extraction, wavelength calibration and cosmic ray corrections are performed. The reduced orders are stored in a multi-dimensional fits file as an intermediate result. Then the blaze function is removed and the orders are connected (from L. Fossati, PHD thesis). The final output of this procedure is a one dimensional spectrum contained in a fits file. Fig. 2.6.

The fully reduced data by the SOPHIE-pipeline was not used because the automatic elimination of the blaze function was not satisfactory and residual features are clearly visible. I used the intermediate results of the SOPHIE-pipeline, where I divided for each order by its corresponding blaze function. Interpolated blaze functions were used for the orders where the wings of the hydrogen lines are present. In this way it was possible to completely remove the blaze function without distorting the wings of the hydrogen lines. I combined the orders using a certain overlapping region, which was averaged. I did not use the edges of the orders because the increased noise of the outermost parts would deteriorate the result. The limits, within which the orders were averaged, were set by visual inspection.

Unfortunately, 2 stars (HD 217423  $V=8.68$  and HD 345444  $V=10.41$ ) have a high  $v \sin i$  and were rather faint, therefore no abundance analysis could be performed for these two stars. Additionally four spectra of HD 49862 (CoRoT Seimon-Target) were obtained by P. Mathias in late September 2009, again, the  $v \sin i$  is too high for abundance analysis purposes but sufficient to estimate the fundamental parameters.

HARPS is a high resolution spectrograph mounted on the 3.6-m telescope at the ESO facility La Silla. The spectrograph was designed for detecting planets and has a resolution of 115000 in High Accuracy Mode (HAM) and 80000 in EGGs mode (general spectroscopy). The former provides a long term accuracy better than  $1 \text{ ms}^{-1}$  and the latter an accuracy of  $10 \text{ ms}^{-1}$ . Spectra of HD 114839 and BD +18 4914 were taken in the framework of the CoRoT-Long Program LP 185D led by E. Poretti as filling targets. The observers of these two stars were J.C. Suárez and K. Uytterhoeven. The HARPS spectra cover a wavelength region from 3780 to 6910 Å in 72 orders. Since the SOPHIE-pipeline was adapted from the HARPS pipeline, the same description of the automatic data reduction pipeline above applies here. Fig. 2.7 shows the automatically reduced spectra. The data reduction was done by M. Rainer (private communication) and was used except for the automatic normalisation, which I did myself in the same way as for the SOPHIE data.

A more detailed description is given in the paper "Looking for a connection between the Am phenomenon and hybrid  $\delta$  Sct -  $\gamma$  Dor hybrid pulsation: Determination of the fundamental parameters and abundances of HD 114839 and BD +18 4914" reprinted in Chap 4.

**Figure 2.6:** Output of the SOPHIE data reduction pipeline of HD 114839 (upper spectrum) and BD +18 4914 (lower spectrum).

**Figure 2.7:** Output of the HARPS data reduction pipeline of HD 114839 (upper spectrum) and BD +18 4914 (lower spectrum).

## Chapter 3

# Frequency Analysis of Individual Stars

By using the high-accuracy photometry of the CoRoT Seismo field and MOST Photometry of four stars I aim to answer the question if there are indeed hybrid pulsating stars. Additional spectroscopy does not indicate binary stars for three stars: HD 49862, HD 114839, and BD +18 4914.

### 3.1 HD 49862

#### 3.1.1 Photometry

HD 49862 is classified in the literature as A5p by McCuskey (1956), indicating a strong K line and a trace of the G band, while the hydrogen lines in the UV were too strong. A more recent determination by Pickles & Depagne (2010) based on photometry in the optical and infrared resulted in a more accurate classification of as F0V. In 2009 four spectra from OHP (Mathias, private communication) were obtained. The results of the analysis of these spectra are discussed in a later chapter.

HD 49862 was observed as one of ten asteroseismology (Seismo) targets in the LRA01. These targets were observed with a sampling of one second yielding approximately 325 000 data points per light curve. The light curve of HD 49862 showed a trend that was removed in the following way. The light curve was split in 3 parts, where for the first and the last part linear fits were subtracted, while a cubic fit was removed for the middle part. Subsequently, a running median outlier clipping was performed. Since the star does not show fast solar-like oscillations the high sampling is not required for frequency analysis. Thus the light curve was binned to 8 minutes, which sets the Nyquist frequency to  $90 \text{ d}^{-1}$ . This does not affect the frequencies to be investigated, but essentially improves the computation speed. SigSpec was applied to this corrected light curve where the significance limit was set to 8. The Fourier

**Figure 3.1:** Part of the binned CoRoT light curve of HD 49862 (top) and DFT spectrum (bottom panel). The dotted vertical lines indicate the CoRoT orbit frequency its harmonic and sidelobes.

transform of the residuals shows an average amplitude of 2 ppm in the range from 43 to 50  $\text{d}^{-1}$ .

Fig. 3.1 shows a part of the reduced light curve and the corresponding Fourier transform, that reveals low frequency  $\gamma$  Dor modes, intermediate modes near 5  $\text{d}^{-1}$  and  $p$  modes typical for  $\delta$  Sct stars from 10 to 22  $\text{d}^{-1}$ . The pulsation spectrum shows a group of  $g$  modes between 1.8 and 3.0  $\text{d}^{-1}$ , which contains the frequency of largest amplitude. A search for period spacings within this group resulted in no pronounced spacing. The second group of frequencies is located between 3.8 and 6.4  $\text{d}^{-1}$ . Due to the high  $v \sin i$  of the star ( $\approx 200 \text{ km s}^{-1}$ ) the rotation frequency may well be located within this group. A rough estimation of the rotation frequency assuming equator on and a radius of  $1.7 R_{\odot}$  results in a rotation frequency of 4.78  $\text{d}^{-1}$ , a radius of  $2 R_{\odot}$  would mean a rotation frequency of 4.1  $\text{d}^{-1}$ . The  $p$  modes are located between 10 and 21.5  $\text{d}^{-1}$  and no constant frequency spacing was found among the  $p$  modes.

The result of the frequency analysis is given in Tab. 3.2, which lists 130 frequencies. The uncertainties of the frequencies, amplitudes and phases were estimated using the formulae given by Kallinger et al. (2008). The total amount of significant frequencies is rather low compared to the high amount of frequencies detected in HD 49434 (Chapellier et al. 2011) that was

observed in the same run and HD 50844 (Poretti et al. 2009) that was observed in the initial run (IRa01). In both of these articles the authors find more than 800 frequencies in their data. Of the low frequencies  $f_{18}$  ( $= 0.114 \text{ d}^{-1}$ ) has the highest amplitude and shows a clear variation in the phase diagram and the amplitude is highest in the last third of the data. This frequency is almost  $1/23$  of the main pulsation frequency  $f_1$  ( $= 2.609 \text{ d}^{-1}$ ; exact ratio  $f_1/f_{18}$ : 22.915). The phase diagram does not show a transit, but more a sinusoidal variation. Thus it is not an artefact due to residual jump nor a planet transit. The explanation by rotation fails due to the high  $v \sin i$ , which was already discussed.

The ratio of the fundamental mode ( $n=1$ ) to the first harmonic ( $n=2$ ) for  $\delta$  Sct stars is about 0.78. Table 3.1 lists tentative identifications of the radial fundamental frequency and the first overtone based on this ratio. The numbers of the frequencies are the same as in Tab. 3.2. I note however, that there can be significant deviations from this ratio due to rotation as Suárez et al. (2006) has shown, and the real radial modes might be missed.

### 3.1.2 Fundamental Parameters

Late September 2009 four spectra were taken by P. Mathias (private communication) using the SOPHIE spectrograph at OHP. The spectra were taken in three consecutive nights beginning in September, 28th with the first spectrum taken in High Resolution (HR) mode with an integration time of 2400 seconds. The next night the High Efficiency (HE) mode was used and the integration time was set to 3600 seconds because the star is a faint object for SOPHIE and the  $v \sin i$  is about  $200 \text{ km s}^{-1}$ , where the HR mode does not provide better information. In the night of September, 30th two spectra were taken with an integration time of 1800 seconds each. The signal to noise of these spectra determined by the Sophie data reduction pipeline (see 2) are 94, 148, 103 and 101, respectively. The four spectra were checked for radial velocity variations, but no significant variation was found and thus the four spectra were combined.

The fundamental parameters were derived by fitting the hydrogen line profiles  $H_\beta$  and  $H_\gamma$ , while the  $\log g$  was derived by fitting the observed spectrum in the range of 5160 to 5200, where the Mg triplet is sensitive to  $\log g$ .  $H_\alpha$  was not used because of heavy contamination by telluric lines. To create the syntheses Kurucz atmospheric models and the code synth3 by O.Khochukhov was used. These codes are described in detail in Chap. 4. For HD 49862 solar abundances were used to compare synthetic spectra to the observations for parameter determination.

Figure 3.2 shows the fitting of the  $H_\gamma$  line (upper panel) and  $H_\beta$  line (lower panel). The hydrogen lines are well represented by the model spectrum with the parameters  $T_{\text{eff}} = 7000 \text{ K}$ ,  $\log g = 3.5$ , while the synthesis with the same

**Table 3.1:** Possible radial fundamental mode and first harmonic identification.

temperature and  $\log g = 4.2$  does not reproduce the observed wings of  $H_\beta$  and  $H_\gamma$  as well. The radial velocity (RV) was determined at 6 different locations in the spectrum with an average of  $34 \pm 5 \text{ km s}^{-1}$ . The projected rotational velocity ( $v \sin i$ ) was determined to  $200 \pm 16 \text{ km s}^{-1}$  using well defined blends.

## Summary

HD 49862 shows clearly  $p$  modes and  $g$  modes, where the dominant mode is a  $g$  mode. These modes are well separated, where the  $g$  modes cluster near 2.6 d<sup>-1</sup>. The  $p$  modes extend from about 12.5 to 20 c/d and contain the fundamental mode and the first overtone based on the frequency ratios. Pulsation modes are detected between these two regimes with maximum amplitudes near the frequency of 5 d<sup>-1</sup>. These modes are not combination frequencies and are hard to explain by theory. The analysis of the spectrum revealed a rapid rotating star, which is likely not a binary. The identification as a hybrid

is now well established for this star. The amplitudes are remarkably low, but were already detected among such stars (see e.g. Altair, Buzasi et al. 2005).

## 3.2 HD 114839 and BD +18 4914

The frequency analysis of HD 114839 and BD +18 4914 was performed in this thesis. For HD 114839 only a short light curve is available with a time span of 9.86 days, which was observed in 2005. Figure 3.3 shows the reduced MOST light curve and the DFT derived in this work and the frequencies that were detected by King et al. (2006) as vertical red lines. My frequency analysis confirms these frequencies, thus they are not repeated here. Note, that the amplitudes of the  $p$  modes are higher than that of the  $g$  modes, which is contrary to HD 8801 (Henry & Fekel 2005). Because HD 114839 was classified as an Am star and shows similar pulsation frequencies as HD 8801, which is an Am star, I performed an abundance analysis of both HD 114839 and BD +18 4914 (see Chap. 4).

BD +18 4914 was observed as a secondary target and guide star within the five observing runs of the planet hosting star HD 209458. The latter is a planet hosting star showing transits in the light curve. Rowe et al. (2006b) analysed the light curve of BD +18 4914 from 2004 and 2005 and found three groups of frequencies, like King et al. (2006) for HD 114839. My analysis of all five light curves generally confirms the existence of two groups of frequencies, where the detection of the third group was of marginal significance (i.e. the frequencies  $14.7$  and  $15.41 \text{ d}^{-1}$  of Rowe et al. (2006b)). The frequency  $14.89 \text{ d}^{-1}$  was a marginal detection and the frequency of  $15.41 \text{ d}^{-1}$  was below my significance threshold, albeit present in the residuals.

The analysis of the combined data sets of all five observing runs again supports the argument for  $14.89 \text{ d}^{-1}$  being real. The frequency  $14.7 \text{ d}^{-1}$  is as well detected but due to the vicinity of the strong orbit artefact I did not consider this frequency as intrinsic. The frequency  $15.41 \text{ d}^{-1}$  was again below the significance threshold, but visible in the residual spectrum.

Significant amplitude variations were found for the  $p$ -modes (or low-order  $g$ -modes), while the amplitudes of the  $\gamma$  Dor modes near  $1.7 \text{ d}^{-1}$  remain nearly constant (see 3.5). The strongest amplitude variation was observed for the frequency  $9.038 \text{ d}^{-1}$ , where the amplitude changed from over  $3 \text{ mmag}$  in 2005 to  $1.4 \text{ mmag}$  in 2008, while at the same time the amplitude of the frequency  $9.267 \text{ d}^{-1}$  reached its maximum but was not detectable in 2005 and 2004. Contrary, the frequency  $9.717 \text{ d}^{-1}$  did not vary much in amplitude. The  $g$  modes changed their amplitudes only marginally.

The reduced light curves of BD +18 4914 are shown in Fig. 3.4 and the frequency analysis of the 2008 data is given in Table 3.3. The phases are calculated for the zero point of the combined data set, which is  $\text{JD} = 2454154$

**Figure 3.3:** Light curve (top) and DFT (bottom) of HD114839. The vertical full lines (red) indicate the frequencies detected by King et al. (2006) and the vertical dashed lines show the position of the MOST orbit frequency and its sidelobes.

+ 1690.020796861. The light curves show episodes of low amplitudes of the  $g$  modes of about 6 days, while during approximately 5 days the low frequency oscillations are pronounced. This behaviour is best visible in the light curve of 2008, where the data quality was best.

**Table 3.3:** Frequency list of BD +18 4914

## Summary

Both, HD 114839 and BD +18 4914 show a very similar distribution of their pulsation frequencies as HD 8801 reported by Henry & Fekel (2005). The frequency analysis of HD 114839 did not yield new results and is therefore not repeated. The frequency analysis of 5 runs of BD +18 4914 showed remarkable amplitude variations of the suspected  $p$  modes near 9 d<sup>-1</sup> but no significant variations of the  $g$  modes. The existence of a third group is not well established because of its vicinity to the MOST orbit artefacts. Again, as for HD 49862 well separated groups of frequencies are observed for these stars. The analyses of their spectra suggest single stars (see Chap.4).

**Figure 3.4:** Reduced light curves of BD +18 4914 from top to bottom: 2004 to 2008.

**Figure 3.5:** Frequency analysis of BD +18 4914. The symbols indicate the frequencies and amplitudes found for each individual data set. The vertical full lines indicate the MOST orbit frequency and its sidelobes. The top panel shows the low-frequency regime, the bottom panel shows the high frequency part of the pulsation spectrum.

### 3.3 HD 73449

The Praesepe star cluster was observed for about one month in 2008 and 2009. Four  $\delta$  Sct stars of these observing runs were analysed and the results published by Breger et al. (2012). Two more pulsating stars, not published yet, were discovered: HD 73449 and HD 73854. The former is a hybrid and the latter is a  $\gamma$  Dor star. HD 73449 was observed in both runs, while HD 73854 was only observed in 2008. The frequency analysis was performed for both stars again with SigSpec to a significance level of 5.0.

Figure 3.6 shows the colour magnitude diagram for Praesepe  $\delta$  Sct stars. The red dots with annotated temperatures indicate the four  $\delta$  Sct stars analysed by Breger et al. (2012). The purple diamonds represent the two program stars. HD 73854 lies just at the red border of the  $\delta$  Sct IS while HD 73449 is close to the centre. HD 73449 was observed in the Geneva photometric system and the calibration of Kunzli et al. (1997) results in  $T_{\text{eff}} = 7200$  K  $\log g = 3.8$  and  $[\text{Fe}/\text{H}] = -0.11$ .

HD 73449 is one of the brighter stars in the Praesepe cluster ( $V = 7.45$  in SIMBAD). The star is a fast rotator with a  $v \sin i = 235 \text{ km s}^{-1}$  (Bernacca & Perinotto 1970) and was classified by Bidelman (1956) as A9Vn and the cluster membership probability is 0.99 (from Webda). A variable radial velocity was reported by Wilson & Joy (1950), who listed 5 measurements that are +45, +28, +19, +34 and +23  $\text{km s}^{-1}$ . The intrinsic brightness of the star and these RV measurements could indicate a binary, however, the high  $v \sin i$  may cause large uncertainties.

The time base of the observations is 31.83 and 17.95 days for 2008 and 2009, respectively. HD 73449 was observed in 2009 both as guide star and direct imaging (DI) target. The results of the data reduction for the GS photometry and a comparison between the GS and DI reduction is shown in Fig. 3.7. The data in 2008 were taken in better environmental conditions, thus the noise is considerably lower than in the 2009 data (upper panel). The DI reduction damps the amplitudes of the  $p$  modes, but leaves a higher orbit amplitude than the guides star reduction (GS) pipeline. However, the average noise amplitude is considerably lower for the DI reduction than for the GS reduction in the range from 47 to 52  $\text{d}^{-1}$  of the data without prewhitening (GS: 39.2 ppm, DI: 23.94 ppm compared to GS 2008: 15.25 ppm). For this reason, the frequencies listed in Tab. 3.4 are given for the 2008 guide star photometry.

HD 73449 is a hybrid that shows a dominant frequency at  $1.317 \text{ d}^{-1}$ , and  $p$ -modes close to the MOST orbit frequency. A combination frequency is present at  $2.452 \text{ d}^{-1}$ , with an amplitude comparable to the other two frequencies,  $f_4$  and  $f_2$ . Hence, it is not clear whether the low frequency is the combination of the two  $p$  modes or one  $p$  mode is the combination of one  $p$  mode and one  $g$  mode, or even this is a coincidence. The time base of the observations is not sufficient to solve this tricky problem.

**Figure 3.6:** Colour Magnitude diagram of Praesepe  $\delta$  Sct stars. My two program stars HD 73449 and HD 73854 are marked by purple diamonds. The ZAMS (thick black line) and the red and blue edge of the  $\delta$  Sct instability strip are indicated by the thin lines (red and blue, respectively).

Apart from the  $p$  modes close to the MOST orbit, a triplet at  $22.6 \text{ d}^{-1}$  is present, where the frequency of the lowest amplitude  $22.644 \text{ d}^{-1}$  may be represented by a combination of  $f_4 + 5f_{22}$ .

**Figure 3.7:** Comparison between the guide star data of HD 73449 of 2008 and 2009 (top panel) and the DI and GS reductions (bottom panel). Instead of overplotting one Fourier spectrum was multiplied by -1 for better visibility.

### 3.4 HD 73854

HD 73854 is considerably cooler than HD 73449 and is located already outside the  $\delta$  Sct IS, but well within the  $\gamma$  Dor IS. The Geneva photometry yields the following parameters:  $T_{\text{eff}} = 6970$  K,  $\log g = 4.3$ , and  $[\text{Fe}/\text{H}] = 0.30$  dex, which are typical for  $\gamma$  Dor stars.

The SigSpec analysis resulted in 149 formally significant frequencies, where the range from 0 to 60  $\text{d}^{-1}$  was investigated. The mean amplitude in the region between 47 and 52  $\text{d}^{-1}$  is 65.5 ppm for the original data and 33.9 ppm after prewhitening with the 149 formally significant frequencies.

HD 73854 shows an amplitude of 21.5 mmag in the Fourier transform that translates to 43 mmag of peak-to-peak amplitude, which means that it is a rather high amplitude for a  $\gamma$  Dor star. The beating effects are very strong and from the light curve (Fig. 3.8.) and phase diagram (Fig. 3.9) a maximum peak-to-peak amplitude of about 0.1 mag can be discerned. No evidence for  $p$  modes were found, where the detection limit is about 120 ppm in the frequency ranges that are not affected by stray light. In the regions heavily affected by stray light a few hardly significant peaks were detected but were rejected due to the increased noise in the vicinity of the MOST orbit frequency. Of the 149 formally significant frequencies 104 remain after the rejection of spurious peaks. These remaining frequencies are listed in Tab. 3.6.

As shown already in Chap. 2, Fig 2.4, the 32 days of observations of the

**Table 3.5:** Sequence of equidistantly spaced periods

| label    | frequency<br>[d <sup>-1</sup> ] | period<br>[d] | significance |

| $f_{11}$ | 1.2504                          | 0.7997        | 587          |
| $f_5$    | 1.1647                          | 0.8586        | 1295         |
| $f_{33}$ | 1.1357                          | 0.8805        | 100          |

2008 MOST light curves yield enough frequency resolution to detect period spacings for  $\ell = 1$  or 2 modes, if the periods are short enough. In my case the main period is 0.756 days hence, a search for period spacings is reasonable. The modified CRF shows two possible period spacings: 0.02 and 0.032 days (see Fig 3.10, bottom panel), neither 0.02 nor 0.032 are consistent with  $\ell = 2$  or 1 modes, respectively. The former is too short for  $\ell = 2$  spacing, while the latter is too short for  $\ell = 1$  and too long for  $\ell = 2$  spacings. Seven periods with significances higher than 90 are consistent with a spacing of 0.021 d, if small deviations and missing modes are admitted. Deviations from constancy are expected from theory due to evolution effects (Dupret et al. 2007; Miglio et al. 2008). In contrast, when I use the spacing of 0.0325 days, only 4 periods are consistent, where the minimum significance is 17.5. Moreover, the spacing of the most significant mode and the second significant mode is about 0.043 (twice 0.021) d.

Tab. 3.5 lists the seven modes consistent with a period spacing of 0.021 d and the result of the modified CRF function is shown in Fig 3.10. The top panel shows the periods versus significances and the dash dotted lines indicate periods spaced by 0.021 days. Note, that the differences of the periods in the table are not necessarily 0.021 days, because missing modes are allowed, hence, the actual differences may be multiples of 0.021 days. I note that the period error, which is calculated based on the frequency resolution, is 0.0175 days at the period of 0.756 days, hence potentially existent shorter period spacings cannot be reliably resolved.

## Summary

The frequency analyses of both Praesepe stars showed that HD 73449 is a complicated case, where two  $p$  modes may excite a combination frequency that is of nearly the same amplitude. In this case it is not clear which frequency is the combination frequency. The amplitudes of the dominating  $p$  modes may be underestimated due to the vicinity to the MOST orbit frequency. This may result in a damping of their amplitudes due to the data reduction. The coincidence may be as well coincidental and to resolve this issue long time base observations would be needed to yield high frequency resolution.

HD 73854 is a  $\gamma$  Dor star just outside the  $\delta$  Sct IS with high amplitude  $g$  mode pulsation. No evidence for  $p$  mode pulsation was found. Seven  $g$  modes form a sequence of equidistantly spaced modes but their spacing is in between the expected spacings of  $\ell = 1$  and  $\ell = 2$  modes.

**Figure 3.8:** MOST light curve (top panel) and DFT spectrum (bottom panel) of the  $\gamma$  Dor star HD 73854. The vertical lines indicate the formally significant frequencies.

**Figure 3.9:** Phase diagram of HD 73854 phased with the dominant mode.

**Figure 3.10:** Top panel: Periods and average period spacing (vertical red full lines and dash dotted blue lines, respectively). Bottom panel: Results of the modified CRF method for detecting period spacings.

### 3.5 Conclusion

The detailed frequency analyses of these five individual stars showed that four stars (HD 49862, HD 114839, BD +18 4914, and HD 73449) are indeed hybrid stars, while the search for  $p$  modes in the  $\gamma$  Dor star HD 73854 resulted in no detection of low-amplitude  $p$  modes. Combination modes were detected but cannot explain all modes in the  $g$  mode regime of these four hybrid stars. Thus, the hybrid nature of these stars is well established while HD 73854 is a pure  $\gamma$  Dor star unless  $p$  modes are masked by the MOST orbit artefacts.

## Abundance Analyses

The abundance analysis of two hybrid pulsators was part of the PhD project and it was published in Hareter et al. (2011).

For this paper I performed the data reduction, parameter determination and the abundance analysis under the supervision of L. Fossati. I wrote the whole paper except for Sect. 5. I produced all figures and tables. The paper is reproduced by permission of the AAS.

### Summary of the Results

The abundance analysis was performed for two hybrid stars, which were previously classified as Am candidates. This analysis was done to infer insights on the connection of chemical anomalies and pulsation. The first star which was discovered as hybrid pulsator reported by Henry & Fekel (2005) was an Am star and the pulsation spectra of HD 114839, BD +18 4914, and HD 8801 are similar. Am stars are characterised by underabundances of Ca, Sc and overabundances of heavy elements. Hence, spectral classifications of Am stars result in different spectral types when using the Ca K line, the hydrogen lines and metallic lines for classification. The diffusion theory (Michaud 1970; Turcotte et al. 2000) is able to explain the observed surface abundances. The  $v \sin i$  of both stars ( $68 \pm 2 \text{ kms}^{-1}$  for HD 114839 and  $38 \pm 2 \text{ kms}^{-1}$  for BD +18 4914) is consistent with Am type stars from literature. Rapid rotation induces rotational mixing and can remove peculiar surface abundances.

The analysis, which was published in Hareter et al. (2011), discovered BD +18 4914 to be a Am star with clear underabundances of Ca and Sc, while the star HD 114839 shows normal chemical abundances within our errors. The analysis included 4 SOPHIE spectra and 2 HARPS spectra for HD 114839 and 2 SOPHIE and one HARPS spectrum for BD +18 4914. The radial velocities were in good agreement for HD 114839 making the existence of a binary component rather unlikely, while for BD +18 4914 a slight deviation of the RV was discovered. Since deviations of approximately  $5 \text{ kms}^{-1}$

may be explained by pulsation (Mathias et al. 2004) the single star hypothesis is still acceptable.

HD 114839 shows an Li line which is consistent with an abundance of -9.8, which is more than one dex stronger as for the sun. Hence, HD 114839 is likely a rather young star, while no Li line is visible for BD +18 4914, which is consistent with a more evolved star.

This investigation showed that the hybrid pulsation phenomenon is not connected to Am type chemical peculiarities, because HD 114839 did not show this type of abundance pattern. Notably, most known Am stars are components of binaries, while HD 8801 Henry & Fekel (2005) and both of the program stars are probably single stars.

## ABSTRACT

$\delta$  Sct– $\gamma$  Dor hybrids pulsate simultaneously in  $p$ - and  $g$ -modes, which carry information on the structure of the envelope as well as to the core. Hence, they are key objects for investigating A and F type stars with asteroseismic techniques. An important requirement for seismic modeling is small errors in temperature, gravity, and chemical composition. Furthermore, we want to investigate the existence of an abundance indicator typical for hybrids, something that is well established for the roAp stars. Previous to the present investigation, the abundance pattern of only one hybrid and another hybrid candidate has been published. We obtained high-resolution spectra of HD 114839 and BD +18 4914 using the SOPHIE spectrograph of the Observatoire de Haute-Provence and the HARPS spectrograph at ESO La Silla. For each star we determined fundamental parameters and photospheric abundances of 16 chemical elements by comparing synthetic spectra with the observations. We compare our results to that of seven  $\delta$  Sct and nine  $\gamma$  Dor stars. For the evolved BD +18 4914 we found an abundance pattern typical for an Am star, but could not confirm this peculiarity for the less evolved star HD 114839, which is classified in the literature as uncertain Am star. Our result supports the concept of evolved Am stars being unstable. With our investigation we nearly doubled the number of spectroscopically analyzed  $\delta$  Sct– $\gamma$  Dor hybrid stars, but did not yet succeed in identifying a spectroscopic signature for this group of pulsating stars. A statistically significant spectroscopic investigation of  $\delta$  Sct– $\gamma$  Dor hybrid stars is still missing, but would be rewarding considering the asteroseismological potential of this group.

## 1. INTRODUCTION

$\delta$  Sct stars are main sequence or evolved stars (up to luminosity class III), which pulsate in low-order radial and non-radial  $p$ -modes with typical pulsation frequencies of 5 to 50 d<sup>−1</sup>. They occupy the lower Cepheid instability strip extended toward the main sequence (see Breger 2000 for a detailed review). The class of  $\gamma$  Dor stars was defined in 1999 by Kaye et al. (1999) and, in contrast to  $\delta$  Sct stars, they pulsate in high-order  $g$ -modes with typical frequencies of 0.3 to 3 d<sup>−1</sup>. The instability strip of  $\gamma$  Dor stars is rather narrow and partly overlaps the larger  $\delta$  Sct instability strip. Given the overlap between the  $\delta$  Sct and  $\gamma$  Dor instability strips, a search for hybrid pulsators began in the last few years, which was driven by the fact that  $p$ -modes are sensitive to the envelope, whereas  $g$ -modes are sensitive to the core. Hence, hybrids are key objects for testing stellar models from core to the photosphere with asteroseismic techniques.

The space missions MOST (Microvariability and Oscillation of STars; Walker et al. 2003), CoRoT (CONvection, ROTation, and planetary Transits; Baglin et al. 2006), and Kepler (Borucki et al. 2010) increased the number of known hybrid stars significantly, because observations of low-frequency pulsation

with low amplitudes are easier from space (see, e.g., King et al. 2006; Rowe et al. 2006; Hareter et al. 2010; Grigahcène et al. 2010; Uytterhoeven et al. 2011).

Am stars are chemical peculiar early F- to A-type stars, characterized by an underabundance of C, N, O, Ca, and Sc, as well as by a general overabundance of Fe-peak and Rare Earth Elements. Am stars do not host large-scale magnetic fields (Aurière et al. 2010) and are often in binary systems (see, e.g., recent review by Iliev & Budaj 2008, and references therein). Compared to the vast majority of the chemically normal stars of the same temperature, Am stars are slow rotators, allowing diffusion processes to produce the chemical peculiarities (Michaud 1970).

The aim of this work is to investigate a potential link between chemical peculiarities such as metallic line A/F stars to the hybrid pulsation. Furthermore, we intend to provide accurate fundamental parameters of our two stars for further modeling of this type of pulsator.

With HD 8801 Henry & Fekel (2005) discovered the first  $\delta$  Sct– $\gamma$  Dor hybrid. Based on the Ca K line intensity relative to hydrogen and metallic lines they classified HD 8801 as an Am star. Hence, it was obvious to check if the two  $\delta$  Sct– $\gamma$  Dor hybrids discovered by Rowe et al. (2006, HD 114839) and by King et al. (2006, BD +18 4914) with MOST photometry share this chemical peculiarity.

\* Based on observations made at the Observatoire de Haute-Provence and with HARPS at the 3.6 m ESO telescope under the Large Programme LP185.D-0056.

HD 114839 (R.A.:  $13^{\text{h}}12^{\text{m}}47^{\text{s}}.43$  and decl.:  $+26^{\circ}52'52''.19$ , epoch 2000;  $V = 8.46$  mag) was classified by Hill et al. (1976) and Clausen & Jensen (1979) as an uncertain Am star. Pribulla et al. (2009) analyzed two spectra obtained at the David Dunlap Observatory in the spectral region of the Mg I triplet at  $\lambda\lambda \sim 5167, 5173$ , and  $5184 \text{ \AA}$ , from which they deduced that HD 114839 is a metallic line star of spectral type F4/5. They measured a  $v \sin i$  of  $70 \text{ km s}^{-1}$ , low enough to allow HD 114839 to be an Am star (Charbonneau & Michaud 1991). BD +18 4914 (R.A.:  $22^{\text{h}}02^{\text{m}}37^{\text{s}}.70$  and decl.:  $+18^{\circ}54'02''.62$ , epoch 2000) is a fainter star ( $V = 10.6$  mag), for which the MOST photometry (Rowe et al. 2006) showed clearly two distinct groups of frequencies. This star was also included in the survey by Pribulla et al. (2009), who derived a spectral type of F5/6 and a  $v \sin i$  of  $40 \text{ km s}^{-1}$ .

As a side comment we want to mention HD 49434, for which a ground-based photometric and spectroscopic campaign was organized and published by Uytterhoeven et al. (2008). However, the hybrid nature of this star has not yet been established beyond doubt, because this star might rotate fast and a spread of frequencies over a larger range may mimic hybrid characteristics. The abundance analysis for this star did not show significant peculiarities.

## 2. OBSERVATIONS AND DATA REDUCTION

Four spectra of HD 114839 were obtained between 2008 April 13 and May 2, while two spectra of BD +18 4914 were obtained in 2008 August 7 and 8 with the SOPHIE spectrograph.

SOPHIE is a cross-dispersed échelle spectrograph mounted at the 1.93 m telescope of the Observatoire de Haute-Provence (OHP). The spectra cover the wavelength range of  $3872\text{--}6943 \text{ \AA}$  without gaps and we used it in the medium spectral resolution ( $R \sim 40,000$ ) mode.

The orders of the individual SOPHIE spectra were averaged, the blaze function removed, and the individual orders merged to a single spectrum. The lowest quality spectrum of HD 114839 was ignored in this process. The removal of the blaze function containing hydrogen lines (HD 114839 and BD +18 4914 in our case) and the subsequent continuum normalization is a challenge for spectra obtained with échelle spectrographs, because for A to F stars these lines extend over adjacent orders. We corrected for the blaze function of orders containing the hydrogen lines by using the artificial flat-fielding technique described, e.g., by Barklem et al. (2002). This approach assumes that the blaze shape of the different échelle orders change smoothly with the order number and one can reconstruct missing blaze shapes by fitting polynomials to continuum points identified in several adjacent orders blue- and redward of the hydrogen line containing order. A two-dimensional polynomial surface is fitted to these empirical blaze functions and the blaze in the orders containing the hydrogen lines is determined by interpolation. The accuracy of this technique is confirmed by an excellent agreement of the normalized hydrogen lines obtained with SOPHIE and HARPS spectrographs (see Figure 1) having a clearly different blaze characteristic and different position of the hydrogen lines within the orders.

The  $v \sin i$  of the two stars ( $\sim 70$  and  $40 \text{ km s}^{-1}$ ) makes the continuum normalization a critical step of the reduction procedure. We normalized the combined, blaze removed orders without the use of any automatic continuum fitting procedure and by comparing with suited synthetic spectra. For wavelengths shorter than the  $H_{\gamma}$  line it was not possible to determine

| BD +18 4914    | 5379.92632    | 92  | 2500          | −47.0                        | 0.9                                   |

**Notes.** The S/N per pixel are calculated at  $\sim 5800 \text{ \AA}$ . Exposure times are given in seconds. BJD indicates the Barycentric Julian Date at the middle of the exposure.

the correct level of the continuum, as there were not enough continuum windows in the spectrum at these wavelengths due to the strong line blending. Therefore, we did not include this part of the spectrum in our analysis. Finally, we obtained a signal-to-noise ratio (S/N) per pixel of 121 at  $\sim 5800 \text{ \AA}$  for HD 114839 and of 56 for BD +18 4914.

Two spectra of HD 114839 were obtained with HARPS two years later on 2010 June 21 and 22, and one of BD +18 4914 in the same year on July 2, in the framework of a program complementary to the extensive monitoring of the hybrid  $\delta$  Sct -  $\gamma$  Dor variables observed with the CoRoT satellite. We processed the HARPS data in a manner similar to the SOPHIE spectra and achieved an S/N per wavelength pixel for HD 114839 of 200 at  $\sim 5800 \text{ \AA}$  and for BD +18 4914 of 92. The HARPS spectra were obtained in the EGGS mode, which delivers a resolution of 80,000.

Table 1 presents the observing log with our measured stellar radial velocities ( $v_r$ ). The star BD +18 4914 might be the primary star in a binary system, given the difference in  $v_r$  obtained between the SOPHIE and HARPS spectra in 2008 and 2010. However, from ground-based observations (Mathias et al. 2004) it is known that  $\gamma$  Dor stars may show significant RV variations due to pulsation. None of our spectra shows spectral lines from a secondary, hence the assumption of a single star or a single-lined binary is justified.

## 3. PARAMETER DETERMINATION AND ABUNDANCE ANALYSIS

To compute model atmospheres we employed a modified version of ATLAS9 (Kurucz 1993), which uses a model of convection based on Canuto & Mazzitelli (1991, 1992). More details can be found in Heiter et al. (2002). The initial atmospheric parameters for HD 114839 were derived from Strömgren photometry by Hauck & Mermilliod (1998) employing the calibration by Balona (1994). We obtained  $T_{\text{eff}} = 7400 \text{ K}$  and  $\log g = 4.20$ . For BD +18 4914 no narrowband photometry was available. Based on a comparison of the spectra we decided to use the same parameters as those used for HD 114839.

In the temperature range of HD 114839 and BD +18 4914, the hydrogen line wings are sensitive to  $T_{\text{eff}}$ , making them very good temperature indicators. We fitted synthetic hydrogen line profiles, calculated with SYNTH3 (Kochukhov 2007), to the

**Figure 1.** Comparison of the  $H\beta$  line profiles (wide gray solid lines) to synthetic profiles calculated with the final adopted  $T_{\text{eff}}$  (solid lines), and uncertainty (dashed lines).

(A color version of this figure is available in the online journal.)

observations. Figure 1 shows the comparison of the observed (SOPHIE for HD 114839, top, and HARPS for BD +18 4914, bottom)  $H\beta$  line profiles for the two stars with synthetic profiles calculated with the stellar  $T_{\text{eff}}$  value of 7100 K for HD 114839 and 6900 K for BD +18 4914. We also show synthetic line profiles calculated with a  $T_{\text{eff}}$  differing by  $1\sigma$  ( $\pm 200$  K).

The Fe I and Fe II excitation equilibrium confirms the  $T_{\text{eff}}$  obtained from the hydrogen line fitting. The atomic line parameters were obtained from the VALD database (Piskunov et al. 1995; Kupka et al. 1999; Ryabchikova et al. 1999). By requiring ionization equilibrium for Fe I and Fe II we derived  $\log g$  values of  $4.0 \pm 0.2$  and  $3.8 \pm 0.2$  for HD 114839 and BD +18 4914, respectively.

Van Leeuwen (2007) reported for HD 114839 a parallax of  $6.24 \pm 0.85$  mas, which puts the star at a distance between 140 and 185 pc. The bolometric correction of 0.033 (see Flower 1996) was neglected, because the uncertainty of the parallax plays a much larger role. From this distance and making use of isochrones by Marigo et al. (2008) (see Section 5), we derived a stellar gravity of  $4.00^{+0.14}_{-0.12}$ , in agreement with what we obtained by imposing the ionization equilibrium.

The median radial velocities and  $v \sin i$  values were derived from fitting synthetic spectral lines to observed profiles. Our measured  $v_r$  values are listed in Table 1 and we obtained  $v \sin i$  values of  $68 \pm 2$  km s $^{-1}$  and  $38 \pm 2$  km s $^{-1}$ , respectively, for HD 114839 and BD +18 4914.

Due to the rather high  $v \sin i$  of both stars, it was not possible to reliably measure equivalent widths for the metallic lines. Therefore, we derived the line abundances by line core fitting

**Figure 2.** Variation of the standard deviation from the mean Fe abundance of both stars as a function of  $v_{\text{mic}}$ , as obtained from the SOPHIE (triangles) and HARPS (circles) spectra. Dashed lines indicate measurements for HD 114839 (offset by 0.2 for better visibility), while full lines connect measurements for BD +18 4914.

(A color version of this figure is available in the online journal.)

in the same way as described by Fossati et al. (2008a). The microturbulence velocity was determined using only Fe lines, because the high  $v \sin i$  and rather low S/N did not allow us to measure enough lines of other elements. We derived the line abundances for the selected Fe lines at different  $v_{\text{mic}}$  values and plotted the standard deviation from the mean abundance as a function of  $v_{\text{mic}}$  (Figure 2). The minimum of this curve gives the  $v_{\text{mic}}$  value, which fits the observation best. From the SOPHIE spectra of HD 114839 and BD +18 4914 we derived  $v_{\text{mic}}$  of 2.6 and 2.9 km s $^{-1}$ , respectively, with an uncertainty of 0.7 km s $^{-1}$ , while from the HARPS spectra we derived  $v_{\text{mic}}$  of 2.8 and 3.6 km s $^{-1}$ , respectively, with an uncertainty of 0.7 km s $^{-1}$ . The values agree within the quoted errors; however, we remark that the HARPS spectra have a better S/N ratio.

The abundances we obtained for the two stars are listed in Tables 2 and 3. We also checked for rare Earth element overabundances, but none was found. Due to the presence of artifacts in the SOPHIE spectra at wavelengths close to the Li I line at  $\lambda 6707$  Å, we were not able to measure the Li abundance from these spectra. The analysis of the Li line was done with the HARPS spectra.

The uncertainty of  $T_{\text{eff}}$  was derived directly from hydrogen line fitting with  $\sigma_{T_{\text{eff}}}$  of 200 K for both stars. Due to the rather low  $T_{\text{eff}}$  and high  $v \sin i$  of the two stars, only a few Fe II lines could be measured compared to Fe I lines resulting in a  $\sigma_{\log g}$  of 0.2. A smaller error for  $\log g$  was derived for HD 114839 using its parallax and evolutionary models as was described at the beginning of this section. Iron was the only element for which we were able to use enough lines of two ionization stages for determining  $\log g$ .

The abundance uncertainties listed in Tables 2 and 3 are the standard deviations of the mean abundances derived from the individual line abundances, which include also the errors from oscillator strengths and continuum normalization (Fossati et al. 2009). The standard deviations of the mean abundances underestimate the actual abundance uncertainty, since uncertainties of the fundamental parameters should also be taken into account. Table 4 displays the fundamental parameters of the two program stars. The error bars used for Figure 3 were computed from the

**Table 2**LTE Element Abundances, in  $\log(N/N_{\text{tot}})$ , for HD 114839 Determined from SOPHIE (Second Column) and HARPS (Third Column) Spectra

| Element | $\log(N/N_{\text{tot}})$ |                  |          |
|---------|--------------------------|------------------|----------|
|         | SOPHIE                   | HARPS            | Sun      |
| Li      | $\dots \ (\dots;0)$      | $-8.91(\dots;1)$ | $-10.99$ |
| C       | $-3.36(\dots;1)$         | $-3.36(\dots;1)$ | $-3.65$  |
| Na      | $-5.82(16;2)$            | $-5.68(11;2)$    | $-5.87$  |
| Mg      | $-4.44(27;9)$            | $-4.55(12;5)$    | $-4.51$  |
| Si      | $-4.22(21;6)$            | $-4.37(23;8)$    | $-4.53$  |
| S       | $-4.60(\dots;1)$         | $-4.75(12;4)$    | $-4.90$  |
| Ca      | $-5.81(22;19)$           | $-5.81(12;12)$   | $-5.73$  |
| Sc      | $-9.11(27;6)$            | $-9.11(05;6)$    | $-8.99$  |
| Ti      | $-7.16(31;10)$           | $-7.10(34;9)$    | $-7.14$  |
| Cr      | $-6.37(21;15)$           | $-6.37(28;10)$   | $-6.40$  |
| Mn      | $-6.63(16;2)$            | $-6.75(01;2)$    | $-6.65$  |
| Fe      | $-4.57(13;79)$           | $-4.57(12;96)$   | $-4.59$  |
| Ni      | $-5.84(21;16)$           | $-5.78(22;16)$   | $-5.81$  |
| Zn      | $-8.04(23;2)$            | $-8.06(29;2)$    | $-7.44$  |
| Y       | $-9.45(21;3)$            | $-9.53(19;3)$    | $-9.83$  |
| Ba      | $-8.95(20;4)$            | $-9.00(06;3)$    | $-9.87$  |

**Notes.** The estimated internal errors in units of 0.01 dex and the number of lines measured for each element are given in parenthesis. For comparison, the last column shows the solar abundances by Asplund et al. (2005). Abundances obtained from just one line have no error ( $\dots; 1$ ).

**Table 3**

As in Table 2, but for BD +18 4914

| Element | $\log(N/N_{\text{tot}})$ |                     |          |
|---------|--------------------------|---------------------|----------|
|         | SOPHIE                   | HARPS               | Sun      |

| Ba      | $-9.57(08;2)$            | $-9.61(02;3)$       | $-9.87$  |

**Note.** The Li abundance is an upper limit.

**Table 4**

Final Parameters of the Program Stars

|             | $T_{\text{eff}}$<br>(K) | $\log g$<br>( $\text{cm s}^{-2}$ ) | $v_{\text{mic}}$<br>( $\text{km s}^{-1}$ ) | $v \sin i$<br>( $\text{km s}^{-1}$ ) |
|-------------|-------------------------|------------------------------------|--------------------------------------------|--------------------------------------|
| HD 114839   | $7100 \pm 200$          | $4.0 \pm 0.15$                     | $2.7 \pm 0.5$                              | $68 \pm 2$                           |
| BD +18 4914 | $6900 \pm 200$          | $3.8 \pm 0.20$                     | $3.2 \pm 0.7$                              | $38 \pm 2$                           |

square root of the sum of squared abundance changes resulting from varying fundamental parameters by  $1\sigma$ .

For iron, e.g., the abundance changes by 0.12 dex, if we change  $T_{\text{eff}}$  by  $1\sigma$  ( $= 200$  K). In the case of  $v_{\text{mic}}$  the abundance changes by 0.09 dex when changing  $v_{\text{mic}}$  by  $1\sigma$  ( $= 0.7$   $\text{km s}^{-1}$ ), while the uncertainty of  $\log g$  increases the abundance error only by 0.01 dex. All these uncertainties add up for the iron

**Figure 3.** Comparison between the abundances relative to the Sun (Asplund et al. 2005) obtained for HD 114839 (circles) and BD +18 4914 (squares) and derived on the basis of the SOPHIE (full symbols) and HARPS (open symbols) spectra. The abundance error bars are explained in the text and are 0.20 dex for HD 114839 and 0.23 dex for BD +18 4914, respectively.

(A color version of this figure is available in the online journal.)

**Figure 4.** Observed SOPHIE spectrum of HD 114839 and HARPS spectrum of BD +18 4914 compared to synthetic spectra around the Sc II line at 5031 Å and of three iron lines at 5027.5 Å. The dashed line is for solar Sc abundance and the full lines are for the abundance derived by us. The spectra for HD 114839 are offset by 0.3 for better visibility.

(A color version of this figure is available in the online journal.)

abundance to 0.20 dex for HD 114839 and to 0.23 dex for BD +18 4914.

The results we obtained from the SOPHIE and HARPS spectra are in comfortably good agreement, confirming our continuum normalization, determination of the fundamental parameters and abundances, and their uncertainties, as shown in Figure 3. Note that the same lines have not always been selected for the same star observed with the two spectrographs.

#### 4. SPECTROSCOPIC CHARACTERISTICS OF HD 114839 AND BD +18 4914

Figure 4 shows the spectral region around the Sc II line at  $\lambda 5031$  Å and of three iron lines at 5027.5 Å for the two stars in comparison with synthetic spectra calculated once with the Sc solar abundance (dashed line) and a second time with the Sc abundance obtained individually for each star (full line). The star BD +18 4914 clearly shows a strong Sc underabundance, while HD 114839 presents a solar Sc abundance. This confirms

**Figure 5.** Mean abundances relative to the Sun of HD 114839 (filled circles) and of BD +18 4914 (filled rhombs), in comparison to the mean abundances of the sample of field  $\delta$  Sct stars (triangles) published by Fossati et al. (2008b) to HD 178327 (open squares) by Balona et al. (2011). The error bars correspond to the standard deviation of the mean abundance.

(A color version of this figure is available in the online journal.)

**Figure 6.** Same as Figure 5 but the results are compared to a sample of  $\gamma$  Dor stars (inverted triangles) published by Bruntt et al. (2008).

(A color version of this figure is available in the online journal.)

BD +18 4914 being an Am star, which is corroborated by the Ca underabundance and the significant overabundance of Ni and Y.

In Figures 5 and 6 we compare the abundances obtained for HD 114839 and BD +18 4914 with the average abundances published by Fossati et al. (2008b) for seven nearby field  $\delta$  Sct stars. This comparison is straightforward because parameters and abundances were obtained with similar methods and codes. We do not find any systematic difference between the mean abundances of the field  $\delta$  Sct stars and of HD 114839, while BD +18 4914 clearly shows its Am nature. Additionally, the results were compared to that of nine  $\gamma$  Dor stars obtained by Bruntt et al. (2008). These authors did not find any typical abundance pattern among  $\gamma$  Dor stars, however they found a larger scatter in the abundances compared to the reference stars. With a reanalysis of two reference stars used by Bruntt et al. (2008), Fossati et al. (2011) showed that the methodology for parameter determination adopted by Bruntt et al. (2008) led them to erroneous results. Consequently, the abundances of the nine  $\gamma$  Dor stars might not be reliable and conclusions from this comparison should be taken with caution.

**Figure 7.** Top: observed HARPS spectrum of HD 114839 compared to the synthetic spectrum (full black line) computed with the Li abundance derived by us in the region of the Li I line at  $\lambda 6707$  Å. Bottom: same as top, but for BD +18 4914 and with the upper limit for the Li abundance. For better visibility the spectrum of HD 114839 is offset by +0.1.

(A color version of this figure is available in the online journal.)

Very recently, Balona et al. (2011) presented the analysis of 10 Am stars observed by *Kepler* of which HD 178327 shows hybrid pulsation. But with a mild overabundance of Ca and Sc, HD 178327 misses an important classification criterion for Am stars where the mentioned elements should be significantly underabundant. The abundances of 14 elements determined by Balona et al. (2011) for this hybrid star are included in our Figures 5 and 6, hence increasing the total number of hitherto spectroscopically investigated hybrid stars to five.

Figure 7 shows the HARPS spectra in the region of the Li line at  $\lambda 6707$  Å in comparison with a synthetic spectrum calculated with the Li abundance obtained for HD 114839 (top). For this star the Li line is clearly visible and leads to an abundance of  $-8.91$  dex. For BD +18 4914 (bottom) the Li line is not visible and we obtain an upper limit of  $-9.80$  dex. The synthetic spectrum for BD +18 4914 is computed with this abundance.

Burkhart et al. (2005) and Fossati et al. (2007) derived the Li abundance in a set of chemically normal A-type stars and compared it to Am stars, concluding that Am stars have a lower Li abundance compared to chemically normal A-type stars. The Li abundance we obtained for HD 114839 and BD +18 4914 reproduces this pattern and strengthens our classification of HD 114839 as a chemically normal star and of BD +18 4914 as an Am star.

A very recent study of  $\delta$  Sct,  $\gamma$  Dor, and hybrid stars (Uytterhoeven et al. 2011) observed by the space mission *Kepler* indicates that possibly two more hybrid candidate stars are chemically peculiar: HD 181206 (Ap or Am) and HD 178327 (Am). For 58 other hybrid candidate stars spectral types based on published spectral classifications are available, but with no indication of peculiarity.

## 5. EVOLUTIONARY STATUS OF HD 114839 AND BD +18 4914

Figure 8 shows HD 114839 and BD +18 4914 in the  $T_{\text{eff}}-\log g$  plane with the respective error boxes derived in Section 3. The figure also shows isochrones from Marigo et al. (2008), for ages between 1 and 1.4 Gyr, from left to right. Solar metallicity was chosen, because we obtained solar Fe abundance for both stars. The error boxes for both stars cover part of the cool  $\delta$  Sct and

**Figure 8.** Position of HD 114839 (full line error box) and BD +18 4914 (dash-dotted line errorbox) in the  $T_{\text{eff}}-\log g$  diagram, in comparison with solar metallicity isochrones by Marigo et al. (2008). The isochrone crossing the center of the HD 114839 errorbox (full line) corresponds to a 1.2 Gyr old isochrone. The dotted line represents 1.0, 1.1, 1.3, and 1.4 Gyr isochrones, from left to right. The zero-age main sequence is also indicated by a full line. The dashed line indicates the red edge of the  $\delta$  Sct instability strip, while the dash-dotted lines show the blue and red edges of the  $\gamma$  Dor instability strip. Both stars fall inside the  $\delta$  Sct- $\gamma$  Dor instability strip.

(A color version of this figure is available in the online journal.)

the  $\gamma$  Dor instability regions and a range of evolutionary stages, masses, and radii (and thereby mean densities).

We used a grid of A-F models<sup>8</sup> provided by one of us (J.C.S.) using the evolutionary code *CESAM* (Morel 1997) to explore the given parameter space in more detail. We used different values for the mass, convection efficiency, and overshoot parameters within ranges typical for these stars (see, e.g., Suárez et al. 2005; Bruntt et al. 2007; Rodríguez et al. 2006b, 2006a, for  $\delta$  Sct and  $\gamma$  Dor stars). Metallicity was fixed to the solar value. Numerics were optimized following the prescriptions suggested by Moya et al. (2008) within ESTA/CoRoT activities.<sup>9</sup> Rotation may play an important role for detailed asteroseismic studies of these stars (Goupil et al. 2005; Suárez et al. 2006), but was not taken into account for the used models.

We found representative models for HD 114839 with masses between 1.52 and 1.71  $M_{\odot}$ , radii between 1.72 and 2.26  $R_{\odot}$ , and ages between 905 and 1405 Myr, respectively. Those for BD +18 4914 were found to have masses between 1.6 and 2.10  $M_{\odot}$ , radii between 2.69 and 4.43  $R_{\odot}$ , and ages between 935 and 1782 Myr. In all cases, the best model fit was obtained for the mixing-length parameter ( $\alpha_{\text{MLT}} = 0.5$ , which is the value found by Casas et al. (2006) for this type of stars using asteroseismic techniques. Overshoot values range from 0.1 to 0.3 for fitting models.

Turcotte et al. (2000) investigated the effect of diffusion on pulsation for upper main-sequence stars. They concluded that young Am stars are stable against pulsation, but become unstable during evolution toward the red edge of the  $\delta$  Sct instability strip. The chemical and evolutionary characteristics of BD +18 4914 presented here are consistent with Turcotte et al. (2000)'s conclusion.

## 6. CONCLUSIONS

Only one hybrid star, HD 49434, was investigated spectroscopically in detail before we started our study of  $\delta$  Sct- $\gamma$  Dor hybrids. However, its hybrid nature is still uncertain and needs confirmation. HD 49434 did not show chemical peculiarities. Hybrid pulsators and stable stars populate the same region of the HR diagram, a situation that is similar to roAp stars (Ryabchikova et al. 2004). For the latter a clear spectroscopic signature could be detected which allows even prediction of pulsation in CP stars (Kochukhov et al. 2002). A similar feature for hybrid pulsators would be extremely important.

A link between the Am phenomenon and hybrid pulsation was speculated, because of the first detected hybrid, HD 8801, being an Am star. Furthermore, early in the literature significant overabundances of iron and/or iron-peak elements were expected as spectroscopic indicators for the driving mechanism. However, our comparison with seven  $\delta$  Sct (Fossati et al. 2008b) and nine  $\gamma$  Dor stars (Bruntt et al. 2008) does not indicate any significant chemical difference between these groups of stars.

With the present paper we nearly doubled the number of spectroscopically investigated hybrid stars, but have not yet succeeded in identifying a particular spectroscopic signature for this group of pulsating stars. For the evolved BD +18 4914 we found an abundance spectrum typical for an Am star, but could not confirm this peculiarity for the less evolved star HD 114839, which is classified in the literature a mild (or marginal) Am star.

$\delta$  Sct- $\gamma$  Dor hybrids pulsate simultaneously in  $p$ - and  $g$ -modes, which are sensitive to the envelope as well as to the core. Hence, they are key objects for investigating A and F type stars with asteroseismic techniques. Accurate values for temperature, gravity, and chemical composition are needed as boundary conditions for stellar models used for fitting the observed eigenfrequencies. We provide such boundary conditions for a seismic modeling of HD 114839 and BD +18 4914, as well as  $\nu \sin i$  and  $\nu_{\text{mic}}$ .

A statistically significant spectroscopic investigation of  $\delta$  Sct- $\gamma$  Dor hybrid stars still is missing, but would be rewarding considering the asteroseismic potential of this group of pulsators.

The authors gratefully acknowledge the development of the tools by C. Stütz and D. Shulyak used for this research and to T. Lüftinger for valuable discussion. ## Chapter 5

# Fundamental Parameters of EXO-Field Stars

Since one goal of this thesis is to find the instability domain of hybrid pulsators, accurate temperatures and luminosities for these stars are necessary. Because of the large distance the photometric indices suffer from reddening, which is a priori unknown and can be different from one star to another.

The shape of the hydrogen lines and the strength of the Ca II lines are in contrast not affected by interstellar matter. Hence, classification spectra allow to derive reddening-free temperatures and luminosities for the program stars.

For 23% (2628 stars) of the LRA01 EXO field stars at least one AAOmega classification spectrum is available allowing determination of temperatures and  $\log g$ . The data were reduced and wavelength calibrated by E. Guenther (private communication). After the frequency analysis of the CoRoT Exo light curves (Chap. 6), 92 bona fide  $\gamma$  Dor stars remain and 37 stars were classified as  $\gamma$  Dor candidates. The number of genuine hybrids is 59 and 57 stars were classified as hybrid candidates. As an example, two spectra of  $\gamma$  Dor stars are shown in Fig. 5.1.

To determine the stellar fundamental parameters from these AAOmega spectra, I developed an IDL software package. The following paragraphs describe this software. The spectral resolution  $R$  of the AAOmega spectra is  $\approx 1400$ , which is sufficient for fitting synthetic spectra to the hydrogen lines and the temperature-sensitive Ca II line at  $\lambda = 3933 \text{ \AA}$ . The classification spectra occasionally show significant outliers probably caused by cosmics, which can cause problems for an automatic normalisation routine. Hence, these obvious outliers were rejected by means of  $4\sigma$  clipping while preserving the spectral lines. To compare the observed spectra to theoretical ones, the spectra need to be normalised. However, the low resolution of the spectra and the large number of spectral lines result in practically no usable continuum points. The normalisation of these spectra is further complicated by the characteristics of the blaze function. How this particular problem was handled is described

**Figure 5.1:** Two AAOmega classification spectra of  $\gamma$  Dor stars. The numbers given in the graphs are the CoRoT identifier.

below.

A grid of synthetic spectra was calculated in four spectral regimes i.e. the K line regime from  $\lambda\lambda$  3850 to 4105 Å including the temperature-sensitive Ca II lines and the hydrogen line  $H_\delta$ , the  $H_\gamma$  regime from 4200 to 4500 Å, the  $H_\beta$  regime from 4600 to 5200 Å, and finally the  $H_\alpha$  region from 6200 to 6800 Å. The parameter space of the syntheses was chosen from  $T_{\text{eff}} = 20000$  K to 5000 K and  $\log g$  from 2.5 to 4.6, with varying step sizes that are listed in Table 5.1. ATLAS9 model atmospheres (Kurucz 1993) and the code synth3 (Kochukhov 2007) were used to calculate the syntheses. The atomic line lists were extracted from the VALD database (Piskunov et al. 1995; Kupka et al. 1999; Ryabchikova et al. 1999).

The software was dedicated to accurately determine the fundamental parameters of  $\delta$  Sct and  $\gamma$  Dor stars. The spectra of cool stars like red giants show weak hydrogen lines and contain molecular bands. Because I used ATLAS9 model atmospheres and the VALD atomic line database, which contains only atomic lines, these stars were excluded from my investigation. Hotter stars were also excluded, because of the limitations of the model atmospheres.

The grid of syntheses is divided into three subgrids, based on two indicative line depth ratios. The two Ca II lines at  $\lambda$  3933.7 Å and  $\lambda$  3968.5 Å are termed K and H after the Fraunhofer scheme. The H line is blended with the  $H_\epsilon$  line and for my purposes the maximum line depth of this blend is selected as H. The hydrogen  $H_\epsilon$  line of stars as hot as mid A to B type is deeper than

**Table 5.1:** Parameters, step sizes and range of the grid of synthetic spectra.

| Parameter range                                       | Step size     |
|-------------------------------------------------------|---------------|
| $T_{\text{eff}} [K] :$                                |               |
| 5000 - 6000                                           | 200           |
| 6000 - 7600                                           | 100           |
| 7600 - 10400                                          | 200           |
| 11000 - 16000                                         | 1000          |
| $\log g :$                                            |               |
| 4.6 - 3.4                                             | 0.2           |
| 3.4 - 3.0                                             | 0.4           |
| 3.0 - 2.5                                             | 0.5           |
| <i>Grid range in <math>T_{\text{eff}} [K]</math>:</i> |               |
| subgrid hot:                                          | 10000 - 20000 |
| subgrid cool:                                         | 5000 - 9800   |
| subgrid intermediate:                                 | 8000 - 15000  |

the Ca H line, while the Ca K line is weak. Therefore, the distinction between hot and cool stars can be done easily and in an automatic way using this line depth ratio, which is referred to as K/H ratio hereafter. The G-Band at  $\lambda$  4305Å becomes stronger for stars beginning with mid F type stars towards later spectral types, which was as well used as a temperature indicator. This ratio is termed G/H <sub>$\gamma$</sub>  hereafter. The best fitting model to a particular spectrum was determined in the following way:

First, the line-depth ratios of the Ca K line and the H <sub>$\epsilon$</sub>  line and that of the G-Band versus the H <sub>$\gamma$</sub>  line are determined to decide which of the three subgrids is appropriate. The determination of the line depth of each of this lines was done by determining the local minimum in a small range centred on the rest wavelength of the respective line. Observed spectra with K/H ratios higher than 0.55 were compared to syntheses of the cool regime ( $T_{\text{eff}} = 5000$  K to 9800 K) regardless of the G-band indicator G/H <sub>$\gamma$</sub> . If the spectrum shows a lower value for K/H than 0.55 and the G/H <sub>$\gamma$</sub>  ratio is less than its critical value, then the hot grid ( $T_{\text{eff}} = 10000$  K to  $T_{\text{eff}} = 20000$  K) is used. If, however, the G/H <sub>$\gamma$</sub>  is larger or equal to 0.5 then the intermediate grid ( $T_{\text{eff}} = 8000$  K to 15000 K) is used. The grids overlap deliberately to avoid edge effects, but are narrow enough to avoid misclassification. The strengths of the hydrogen lines are maximum at A0 and are becoming weaker towards both cooler and hotter spectral types. Therefore, the software may misclassify a hot for a cool star or vice versa. The simplest way to avoid such problems is to restrict the search regime based on the mentioned line depths ratios. This first rough temperature estimation is not sensitive to the radial velocity as no exact wavelengths were

assumed for reference but rather the local minima of the respective line within a certain range were used as the line depths.

Second, after the determination of the proper subgrid, the radial velocity (RV) is determined by shifting the observed spectrum with respect to a model spectrum. As a first guess, the model spectrum with the mean temperature of the parameter space was chosen and  $\log g$  was fixed to 4.2. The spectrum was shifted from  $-200$  to  $200 \text{ km s}^{-1}$  in  $10 \text{ km s}^{-1}$  steps. The best fitting RV is determined as the shift for which the deviation between the observation and synthetic spectrum is minimised. The determination of the RV is done for each spectral regime (i.e.  $H_\alpha$ ,  $H_\beta$ ,  $H_\gamma$ , and Ca K) separately and the observations are individually corrected for RV. Hence, the effect of errors in the wavelength calibration is mitigated.

Third, the best fitting synthetic spectrum is determined and Fig. 5.2 illustrates by means of the  $H_\alpha$  line how this is accomplished in detail. The part of the spectrum shown is divided by its average intensity for better visibility (black thick line). The observed spectrum is then normalised in the following way: It is divided by a test synthesis of the corresponding subgrid, shown by the thick red line. The result of this division is indicated by the thin blue line. A low-order polynomial (order 1 for hydrogen lines and order 2 for Ca K, indicated by the maroon straight line) is fitted to the pseudo-continuum points (green open circles) and the quotient (thin blue line) is divided by this polynomial. The result is indicated by the dashed grey line. Subsequently, the standard deviation is compared to the point to point scatter for points at the wings of the hydrogen line (orange asterisks).

The ratio of the standard deviation ( $\sigma$ ) and the point-to-point ( $p$ ) scatter is defined as D-value:

$$D = \frac{\sigma}{p}, \quad (5.1)$$

with

$$p = \sqrt{\sum_{i=1}^{n-2} \frac{(x_i - x_{i-1})^2}{2} + (x_0 - x_{n-1})^2}, \quad (5.2)$$

where  $p$  is defined as the mean difference of consecutive data points and  $n$  denotes the number of data points of the data set,  $x_0$  is the first data point. When the synthesis represents the observation perfectly, the standard deviation and point to point scatter reflect the uncorrelated noise of the data and thus their ratio would be 1.0. If however, the hydrogen lines of the synthetic spectrum do not represent the observations well, then the standard deviation is dominated by a systematic error and the ratio is larger than 1.0.

The cores of the lines are deliberately excluded for this calculation, because my model spectra do not fit the hydrogen line cores. This procedure is done for the entire subgrid of model spectra. Due to systematic effects such

as normalisation problems, line misfits or telluric lines, the ideal situation of  $D = 1$  (perfect fit) is never achieved. Thus, the synthesis that yields the lowest  $D$  ratio is adopted as the best fitting model spectrum, but the absolute value of  $D$  is irrelevant. The same procedure is done for the  $H_\beta$ ,  $H_\gamma$ , and Ca K line.  $T_{\text{eff}}$  and  $\log g$  of these four best fitting syntheses are averaged and the model spectrum is considered as best fitting synthesis whose parameters are closest to the average  $T_{\text{eff}}$  and  $\log g$ .

After this first determination of the best fitting synthesis, a second iteration is done because an incorrect RV could lead to wrong results. Hence, the described procedure is repeated once again, but for the RV determination the now determined best fitting model spectrum is used to correct for RV. Experience shows that this second iteration approach improves the agreement of the four individual results derived from  $H_\alpha$ ,  $H_\beta$ ,  $H_\gamma$ , and the K line. Fig. 5.3 shows the  $D$ -values calculated for about 300 syntheses of the subgrid. The inset shows a zoom into the global minimum. The synthesis No.128 yields the best  $D$ -value, but also the No. 127, 129, and 130 fit the data nearly as well. Two syntheses with a higher temperature but different  $\log g$  are also possibly representative (No. 134 and 135). The figure also demonstrates the importance of confining the search domain of model spectra on the basis of the Ca K line, since the local minima towards higher temperatures (these are syntheses with higher indices on the abscissa) tend to fit better with lower surface gravity. In other words, the hydrogen lines of hot giants are narrow and thus fit that of cooler main sequence stars as well, while the Ca K line depth is completely different for hot and cool stars.

The final results consist of four pairs of  $T_{\text{eff}}$  and  $\log g$  for each individual spectral region and the final set of parameters is derived by averaging. The  $v \sin i$  was fixed to  $100 \text{ km s}^{-1}$  because it turned out that it is not possible to derive reliable values for  $v \sin i$  for data with such low spectral resolution. The  $v \sin i$  fitting routine interprets lines (e.g. the Mg triplet near  $\lambda 5170 \text{ \AA}$ ) as noise and thus the  $v \sin i$  cannot be estimated with sufficient accuracy. Following this approach a reliable error determination is not straight forward. The consistency of the four temperature estimates can be assessed by the standard deviation. In the regime of  $\gamma$  Dor stars the determination of  $\log g$  poses an awkward problem, since the wings of the hydrogen lines change only slightly with changing  $\log g$ . Therefore, a high S/N is required to detect significant differences. In particular, metallic lines would be more useful but unfortunately, the S/N of the AAOmega spectra is generally too poor to fit syntheses to such lines.

Typical temperature errors from high resolution spectroscopy are of the order of 200 K for stars at  $T_{\text{eff}} = 7000 \text{ K}$  and the  $\log g$  errors are typically 0.2 dex when using the ionisation equilibrium (see for example Chap. 4), which is generally not possible for low-resolution spectroscopy, as discussed above. To assess the errors of the method a subset of 613 spectra from the ELODIE data

base (Prugniel & Soubiran 2001) was chosen and my fundamental parameter pipeline was applied to them. As I was interested in F and A type stars, the test of my method involved 613 spectra in the range of  $T_{\text{eff}} = 5600$  and  $8000$  K, where no constraint on the  $\log g$  was made. Figures 5.4 and 5.5 show the comparison of my results to that of the ELODIE determination (Katz et al. 1998) in the top panels, the same but for literature parameters provided in the ELODIE data base (middle panels). Finally, the results of the ELODIE-Pipeline are compared to the literature parameters (bottom panels). While Fig. 5.4 shows the comparison for effective temperature, Fig. 5.5 shows the same for  $\log g$ . The ELODIE spectra cover the blue wavelength range from  $\approx \lambda 3900$  Å onward, the AAOmega spectra cover  $\approx \lambda 3750$  Å. Hence, a reliable normalisation of the Ca K region could not be achieved by my software for the ELODIE spectra and the resulting parameters were ignored. Only the fitting of the three hydrogen lines  $H_\alpha$ ,  $H_\beta$ , and  $H_\gamma$  were used. For 12 ELODIE spectra the determination of the proper subgrid could not be done based on the Ca K line, these spectra yield too hot temperatures and are not shown in the plot.

The results for  $T_{\text{eff}}$  are generally in good agreement. 79.4% of the temperatures fit within 5% deviation, and 94.1% cases agree within 10% deviation. The comparison to the  $\log g$  values are clearly worse. A clear systematic trend is present where my  $\log g$  estimation is lower than the ELODIE and literature values. Since I used only the hydrogen lines and these lines are hardly sensitive to changes in  $\log g$ , the deviations in  $\log g$  are huge.

If the Mg-triplet or the Ca K line are considered, the  $\log g$  estimates are useful only for stars with cooler temperatures, because these features vanish in hotter stars. On the other hand, the Mg-triplet disappears in the noise if the S/N ratio is poor, preventing accurate  $\log g$  determinations based on the Mg triplet for a large sample of spectra.

Some spectra in my sample are affected by fringing, of which Fig 5.6 shows three examples. The pattern is perceivable as waves in the spectra. It is not beneficial to remove this fringing pattern by fits because the hydrogen lines are heavily distorted by the fringing effect and useless for model fitting. I found that such spectra still allow a rough estimate of the temperature by visual inspection and are therefore sufficient to differentiate between  $\gamma$  Dor and SPB. Stars with such spectra were excluded from further investigation.

Tables 5.2, 5.3, 5.4, 5.5 and 5.6 list the results of my parameter determination via the fitting of model spectra for the  $\gamma$  Dor,  $\gamma$  Dor candidates, the hybrids, the hybrid candidates and the  $\delta$  Sct stars. The column CID refers to the CoRoT identifiers, in the second column the cross reference to the USNO-B1 catalogue identifier is given, the column  $T_{\text{eff}}$  and  $\log g$  give the average of the four individual  $T_{\text{eff}}$  and  $\log g$  of the best fitting model spectra described above and the column  $\sigma T_{\text{eff}}$  and  $\sigma \log g$  display the corresponding standard deviation. The S/N of each spectrum is given in the column S/N. It was estimated by A. Kaiser (PhD thesis in prep.) using the DER\_SNR algorithm by

**Figure 5.2:** Fitting of the  $H_\alpha$  line. The thick red line shows the best fitting synthesis, the thick black line illustrates the observed  $H_\alpha$  region. The thin blue line shows the ratio of the observation and the synthesis, the maroon straight line indicates a linear fit to the pseudo-continuum points that are indicated by the open green circles. The dashed line shows the division by the linear fit and the orange asterisks indicate the points for which the standard deviation and point-to-point scatter were evaluated.

Stoehr et al. (2007) between  $\lambda$  4500Å and  $\lambda$  5400Å excluding 200Å centred on the  $H_\beta$  line. The column V lists the apparent magnitude in the V filter in magnitudes and finally, the column Sp.T. list the spectral types derived by Guenther et al. (2012) or Sebastian et al. (2012). Footnotes indicate problems with the spectra and are explained at the bottom of the tables. These stars were excluded for further investigation.

**Table 5.2:** Fundamental parameters of  $\gamma$  Dor stars, derived by me, compared to their spectral type from Guenther et al. (2012) and Sebastian et al. (2012).

<sup>e</sup> eclipsing binary; <sup>gha</sup>  $H_{\alpha}$  deviates in  $\log g$ ; <sup>F</sup> fringing; <sup>g+</sup>  $\log g$  consistent;

<sup>t+</sup>  $T_{\text{eff}}$  consistent; <sup>g-</sup>  $\log g$  inconsistent.

**Figure 5.3:** Ratio of the standard deviation and the point-to-point scatter (D-value) for a subset of the parameter range. The synthetic spectra are referred to by index (abscissa). The formally best fitting synthesis is indicated by the red asterisk. The inset shows a zoom-in around the best fitting synthesis.

**Figure 5.4:** Comparison of the results of my temperature determination (abscissa) to 1) the results of the ELODIE-Pipeline (top panel), 2) the literature values (taken from the ELODIE fits headers) in the middle panel and the ELODIE versus the literature values (bottom panel). The dotted lines indicate the standard deviation for each data point. The filled circles represent the spectra flagged with the quality flag 4, 3, or 2. The dashed and dash dotted lines indicate 5% and 10% deviations and the full red line marks the zero line to guide the eye.

**Figure 5.5:** Same as Fig. 5.4 but for  $\log g$ .

**Figure 5.6:** Examples of fringing among the AAOmega spectra.

**Table 5.3:** Fundamental parameters of  $\gamma$  Dor candidate stars compared to their spectral type from Guenther et al. (2012) and Sebastian et al. (2012).

## Conclusion

The determination of the fundamental parameters was done in order to place these stars in the HRD and to allow the statistical investigations in the following sections. The  $\log g$  values are generally subject to large errors, because for stars cooler than 8000 K the hydrogen lines are only weakly sensitive to  $\log g$ . Nevertheless, the derived values in  $\log g$  are accurate enough to differentiate between dwarfs and giants. Thus, it is shown that hybrid stars are not giants. The comparison to the spectral classification by Sebastian et al. (2012) and Guenther et al. (2012) shows a satisfactory agreement.

## Chapter 6

# Frequency analysis of the LRa01 EXO data

In order to safely classify a star as a hybrid a careful frequency analysis is required. A simple classification based on frequency regimes alone may easily misclassify eclipsing binaries or rotating stars as  $g$  mode pulsator. Not only these effects, but also prevailing spurious frequencies caused by residual artefacts in the data can easily mislead such a simple classification. Combination frequencies are another source of misclassification. Therefore, the frequency solution for each star was analysed carefully to avoid such mistakes and firmly establish the existence of  $g$  modes.

The frequency analysis was performed using the tool SigSpec (Reegen 2007) in the version 2 of October 3rd, 2007. This is an optimised version compared to the version 1 where the runtime was significantly reduced. SigSpec performs a multi-sine fit and does not rely on prewhitening. Prewhitening is only used to determine the next frequency to be included in the multi-sine fit. SigSpec was developed by P. Reegen and a user manual is provided in the CoAst-volume 163 (Reegen 2011).

In several publications authors compared SigSpec-results to Period04 results with an almost perfect agreement. In this work Period04 was not used since the amount of data sets and the number of data points of each set makes the analysis time-consuming.

The CoRoT data are already described in Chap. 2. The frequency analyses of all sample stars were carried out in the frequency regime from 0 to  $84 \text{ d}^{-1}$ . The CoRoT orbit period is present in all light curves as well as its harmonics. In the low-frequency regime there is weaker a  $2 \text{ d}^{-1}$  signal which is due to the crossing of the South Atlantic Anomaly (SAA) twice a day. Frequencies lower than  $0.5 \text{ d}^{-1}$  are mainly affected by residual aperiodic or quasi-periodic artefacts after our jump-removing pipeline. The lowest frequencies are therefore ignored in this work, except for the cases where a clear variability is visible in the light curve.

The frequency determination is rather easy because the artefacts are well known and the aliasing does not pose a significant problem. SigSpec identifies usually about 150 frequencies in a  $\gamma$  Dor data set that are formally significant. A threshold of significance 6 was chosen. The  $\gamma$  Dor data sets were carefully searched for possible  $p$ -modes. Of the initially classified  $\gamma$  Dor stars, 6 cases showed  $p$  modes and were reclassified as hybrids, accordingly.

## 6.1 $\gamma$ Dor stars

Of the initial 418  $\gamma$  Dor candidate stars I selected only stars for which AAO classification spectra are available enabling me to determine their fundamental parameters. In this fashion, the sample reduces to 132  $\gamma$  Dor candidate stars, for which the frequency analysis is performed. Subsequently, 92 pure  $\gamma$  Dor stars and 30 remaining candidates were identified and 10 stars were rejected because of uncertain fundamental parameters due to unusable spectra. Table 5.2 lists their CoRoT IDs and as cross-reference their USNO-B1 identifiers. Additionally, their effective temperatures, surface gravities, apparent magnitudes and their spectral types are given. The spectral types were derived by Guenther et al. (2012) and Sebastian et al. (2012).

Stars, where the  $\gamma$  Dor classification is unclear are still kept after the frequency analysis. The prevailing reason for this is that their frequency content is not convincing enough to safely identify them as pulsation frequencies. Speculative differential surface rotation or stellar activity could produce signal in this frequency regime. If this was the case then harmonics of the rotation periods are expected and such harmonics are indeed observed in many cases. But due to the lack of additional information, such as high-resolution time-series spectroscopy, the rotation hypothesis is based only on the light curve. A few stars show only two or three frequencies in the  $\gamma$  Dor regime and no further signal. Thus, such stars are classified as candidates as well for the above mentioned reason. Moreover, there are stars too hot for  $\gamma$  Dor but too cool for SPB that show low-amplitude signal. These stars were as well classified as candidates but might represent a new class of low-amplitude variables. These stars are listed in Table 6.1.

The star CID 102597681 shows rather high amplitudes and a typical  $\gamma$  Dor pulsation spectrum. Additionally, the light curve shows a transit with a period of 20.82 days. Carone et al. (2012) classified this case as planet transit candidate and obtained spectra for this star (among other transit candidates). It turned out that this system constitutes a SB3 system with a bright A-type star. This star dominates the light and therefore the temperature determination was wrong. For further investigations (e.g.  $T_{\text{eff}}$  -  $\log P$  diagram) this star was excluded. Two more stars are listed in the catalogue by Carone et al. (2012), that are: CID 102738809 and CID 102694263. I suggest one more eclipsing

**Figure 6.1:** Three types of  $\gamma$  Dor stars. Top left and right panels: 1) high amplitude  $\gamma$  Dor stars (CoRoT 0102603266), middle panels: 2) HD 49434-like  $\gamma$  Dor star example and 3) lower panels: Nonsinusoidal light curves with tightly spaced frequencies.

binary candidate, which is CID 102726709, where the phase diagram folded with the frequency  $0.7862 \text{ d}^{-1}$  shows a weak bump which might be due to an eclipse. This star is not present in the catalogue of Carone et al. (2012).

Among the stars classified as  $\gamma$  Dor there are differences in the pulsation spectra. Based on the Fourier spectrum three subgroups can be defined:

Type 1:  $\gamma$  Dor stars where the frequencies are centred around a main peak, occasionally side clusters of frequencies appear.

Type 2: HD 49434-like  $\gamma$  Dor stars where the frequencies spread over a large range

Type 3: characterised by nonsinusoidal light curve with closely spaced frequencies and harmonics.

Fig.6.1 shows one example of each of these types.

### Search for Period Spacings

I performed a systematic search for period spacings among the  $\gamma$  Dor stars. For this aim, I modified the Comb Response Function (CRF) of Kjeldsen et al.

(1995), which is used for detecting frequency spacings in solar-like pulsators, to accommodate needs for regular period spacings. Instead of the power spectrum I use the significance spectrum in period and the terms of  $0.5\Delta P$  ( $\frac{1}{2}\Delta\nu$  in the original article) were omitted.

In order to detect period spacings with such an algorithm a constant period step size is required. SigSpec and other Fourier Analysis algorithms calculate the Fourier transform on a regular grid in frequency and thus yield an unevenly spaced period spectrum when turning the frequencies into periods. Hence, I adapted the part of the code of SigSpec (Reegen 2007), which implements the evaluation of the significance for each frequency step, to evaluate the significance at each given period instead of frequency step. Tests were performed to ensure correct results by comparing to the output of the unaltered SigSpec code to this altered code.

Equations 6.1 and 6.2 show how my modified version of the Comb Response function was implemented.  $p_{max}$  is the period of maximum significance,  $n \in \{-2, -1, 0, 1, 2\}$  and  $S(x)$  denotes the significance spectrum at the period  $x$ .

$$CRF_{mult}(\Delta p) = \prod_{n=-2}^2 S(p_{max} + n\Delta p) \quad (6.1)$$

$$CRF_{sum}(\Delta p) = \sum_{n=-2}^2 S(p_{max} + n\Delta p) \quad (6.2)$$

Both, the sum and the product are employed because of 1) avoiding the misinterpretation of the spacing between the main peak and the second strongest peak. The multiplication solves this problem whereas the function employing the sum shows a peak at this spacing. 2) Avoiding the loss of a constant period spacing if one mode is missing. The sum of significances now overcomes this problems, whereas the product becomes zero if one factor is zero. The ordinate is arbitrary and the following normalisation was performed for convenience:

$$CRF_{mult,norm}(\Delta p) = \frac{CRF_{mult}(\Delta p)}{\max(CRF_{mult})} \quad (6.3)$$

$$CRF_{sum,norm}(\Delta p) = \frac{(CRF_{sum} - \min(CRF_{sum}))}{\max(CRF_{sum})} \quad (6.4)$$

Figure 6.2 shows an example of the CRF. In the upper panel the resulting sum and product are displayed. Both functions show a peak at 0.009. The bottom panel shows the periodogram in significance. The vertical dotted lines are centred on the most significant peak and spaced by 0.009 d, as was determined by the CRF.

**Figure 6.2:** Detection of period spacings. Upper panel: Results of the CRF using both, multiplication and sum of significances. Lower panel: Periods spaced uniformly with the detected spacing are indicated by the vertical red dashed lines. The horizontal line displays a significance level of 5.46. The significance is plotted in logarithm for better visibility.

The period spacings found are generally very short. From theory we would expect a period spacing of about 1 hour (3600 s) for  $\ell = 1$  modes. (see Miglio et al. 2008). The spacing shrinks for higher  $\ell$  values, but most of the detected spacings are still too short for  $\ell = 2$ . Higher degree modes are possible, however they are supposed to suffer from cancellation effects and therefore their amplitudes should be very small or not detectable.

Moreover, the detection of a period spacing implies the same  $\ell$  value for all the uniformly spaced modes. This is a questionable assumption, which needs to be confirmed by spectroscopic mode identification. The EXO field stars are, however, too faint to obtain time-resolved spectroscopy with accessible instruments. Miglio et al. (2008) have shown that due to evolution effects the period spacing deviates from a uniform one (ZAMS stars) and becomes periodic itself in the radial order for evolved stars.

The effect of rotation is even worse than evolution effects. The rotation period of  $\gamma$  Dor stars can well be of the order of the pulsation period and the rotational splitting for  $g$  modes is not symmetric. Again, this leads to a deviation from a strictly uniform spacing. This matter was discussed by Dupret et al. (2007) and is discussed in more detail in Chap. 7. Despite all adversities, it had to be verified for not overlooking important details. Table 6.2 lists the results of the investigation for period spacings.

**Table 6.1:** 5 hot  $\gamma$  Dor candidates.

| CoRoT ID   | $T_{\text{eff}}$<br>[K] | $\log g$<br>[ $\text{cms}^{-2}$ ] | Main Frequency<br>[ $\text{d}^{-1}$ ] |
|------------|-------------------------|-----------------------------------|---------------------------------------|
| 0102581832 | $8300 \pm 200$          | $3.733 \pm 0.231$                 | 1.231                                 |
| 0102612288 | $8550 \pm 191$          | $4.2 \pm 0.346$                   | 0.686                                 |
| 0102654138 | $8300 \pm 476$          | $3.75 \pm 0.7$                    | 1.943                                 |
| 0102685143 | $8250 \pm 100$          | $4.267 \pm 0.306$                 | 0.387                                 |
| 0102701987 | $8450 \pm 100$          | $4.2 \pm 0.346$                   | 0.208                                 |

Stars hotter than 8000 K showing low frequency signal were detected. These stars were classified as  $\gamma$  Dor candidates. In three cases, the mask of such stars contain more than one star, hence it is possible that the pulsation does not originate from the component which is dominating the total light. Five stars, however, have no contaminating background (or foreground) stars within their mask. The amplitudes of the  $g$  mode like frequencies are often below 1 mmag and sometimes of the order of a few hundred ppm. The suspected pulsations are multi-periodic, where harmonics are often present. This result is not unique for my sample, and was already reported by Uytterhoeven & WG#10 (2011) for *Kepler* observations. The convective flux blocking mechanism that is considered so far as the best explanation for the driving of  $g$  modes, is unlikely to be effective for such stars, since the base of the convection zone is closer to their surfaces. However, a very recent study of stochastically excited  $g$  modes may explain these frequencies (Shiode et al. 2012).

The DFT spectra of the 5 hot stars ( $T_{\text{eff}} \geq 8000$  K) are shown in Fig. 6.3. The parameters of the five presented stars are listed in Table 6.1

**Figure 6.3:** Fourier transforms of the 5 hot  $\gamma$  Dor candidates listed in Table 6.1. The order from top to bottom is the same as in the table.

**Table 6.2:**  $\gamma$  Dor stars with  $T_{\text{eff}}$   $\log g$  dominant frequency and detected period spacings in days of  $g$  mode.

## 6.2 $\delta$ Sct - $\gamma$ Dor hybrid stars

The first report on *Kepler* observations of  $\gamma$  Dor and  $\delta$  Sct hybrid stars was published by Grigahcène et al. (2010). These authors suggested a new classification scheme based on the frequency of maximum power, because the first data of *Kepler* implied that there are practically no pure  $\delta$  Sct or  $\gamma$  Dor stars. Contrary, I found in the CoRoT data pure  $\gamma$  Dor and pure  $\delta$  Sct thus their proposed scheme was not applied. The definition of hybrid star is not so straight forward as it may appear at first sight.  $\delta$  Sct stars are known to pulsate not only in  $p$  modes but also in low-order  $g$  modes or mixed modes (eg. FG Vir, Breger et al. 2005).  $\gamma$  Dor stars pulsate in high-order  $g$  modes, thus in this thesis hybrid stars were defined as stars which pulsate in the low frequencies as  $\gamma$  Dor and  $\delta$  Sct in the high frequency regime at the same time. Hence two conditions must be met: 1) high-order  $g$  modes and 2) low-order  $p$  modes.

The distinction between  $g$  and  $p$  modes is the key. The frequencies of  $p$  modes depend on the evolutionary state of the star and on  $T_{\text{eff}}$ , which means the knowledge of the stellar fundamental parameters is imperative to safely distinguish  $p$  and  $g$  modes. The widely used criterion of  $5 \text{ d}^{-1}$  serves as a first guess when the stellar parameters are known with large uncertainties or even unknown. By no means is the criterion of  $5 \text{ d}^{-1}$  valid for a distinction between  $p$  and  $g$  modes for all stars.

The pulsation constant  $Q$  provides an estimate for the radial fundamental frequency, i.e. the lowest frequency of a  $p$  mode, for which  $Q \approx 0.033 \text{ d}$ .  $g$  modes have higher  $Q$  and other  $p$  modes lower  $Q$  values. The definition of  $Q$  can be found e.g. in Handler & Shobbrook (2002, equation 1 therein) and is given in Eq. 6.5:

$$\log Q = C + 0.5 \log g + 0.1 M_{\text{bol}} + \log T_{\text{eff}} + \log P, \quad (6.5)$$

where  $C = -6.456$ ,  $M_{\text{bol}}$  denotes the absolute bolometric magnitude and  $P$  is the period of the considered mode. In the study of Breger et al. (2012) the frequencies were normalised to their  $Q$ -values (Fig.3 therein) in order to compare different  $\delta$  Sct stars of the Praesepe cluster.

Since  $\delta$  Sct stars show often combination frequencies they can mimic  $g$  mode pulsation. Emphasis was put on this subject and stars showing only combination frequencies in the  $g$  mode regime were not classified as hybrids. To safely identify high-order  $g$  modes, not only the combination frequencies have to be excluded, but also rotation can play a significant role. The space instruments are sensitive enough to potentially show rotation effects. Furthermore, amplitude modulation of  $p$  modes may produce as well frequencies in the  $g$  mode regime.

The situation becomes even more complicated, when it comes to disentangle low-order  $g$  modes from high-order  $g$  modes.  $\delta$  Sct stars are known to pulsate not only in  $p$  modes but also in low order  $g$  modes or mixed modes.

In contrast,  $\gamma$  Dor stars only pulsate in high-order  $g$  modes, which excludes a  $\delta$  Sct star pulsating in low-order  $g$  modes from my hybrid definition.

Based on these premises 57 genuine hybrids and 53 candidates were found. The high number of candidates, which is nearly the same as the genuine cases, is due to the above mentioned reasons. In practice, the distinction between various types of pulsation modes can be easy (e.g. HD 114839 BD +18 4914) or very complicated (e.g. HD 49434).

### 6.3 Results and Comments for Individual Stars

The following tables (Tab. 6.3, 6.4, 6.5 and 6.6) contain the results of the frequency analysis for each individual star classified as  $\gamma$  Dor,  $\gamma$  Dor candidate, hybrid and hybrid candidate, respectively. In the second column of the tables, labelled "Groups of frequencies" the centres frequency of the groups in the Fourier transform are given, while for the hybrids and hybrid candidates the number of such groups is listed instead. In the column "DFT Noise" the average amplitude of the Fourier transform in the range of 47 to 52  $\text{d}^{-1}$  is given in micromagnitudes. The column "Mask" contains information about the point spread function (PSF) within the photometric mask, from which the intensities are determined. 0 signifies a clean PSF, 1 means that a clear second peak (a second star) is present within the photometric mask, while 2 signifies a distorted PSF, where the PSFs of two stars might have merged. The first number in the column "Number of frequencies" denotes the number of independent frequencies, while the second number indicates the total of formally significant frequencies. For example, 32/55 means that 32 out of 55 are found to be independent frequencies. The column "type" indicates for the  $\gamma$  Dor stars and  $\gamma$  Dor candidates the type of pulsator based on their DFT spectra.

In the case of hybrids and hybrid candidate the type 'G' denotes a star, where the  $\gamma$  Dor modes are dominant and the letter 'D' indicates that  $p$  modes ( $\delta$  Sct modes) show the higher amplitudes.

Abbreviations used within the tables are:

- LC: light curve
- CJD: JD - 2451545
- DFT: Discrete Fourier transform
- S/N: Signal to noise
- UV: Ultra-violet
- Freq(s): frequency (-ies)

Table 6.3: Notes on individual bona fide  $\gamma$  Dor stars.

## 6.4 Conclusion

The frequency analysis of this chapter has shown that the numbers of genuine hybrids and still uncertain cases (termed hybrid candidates) are about the same. This shows the difficulty of detecting true hybrid stars. Of the 59 genuine cases, 23 show dominant  $\delta$  Sct pulsation and 17 show dominant  $\gamma$  Dor pulsation and 19 are unclear cases. Including the candidates the numbers change to 54  $p$  mode dominant and 18  $g$  mode dominant stars and 44 unclear cases.

The frequency analysis of  $\gamma$  Dor stars has revealed three different types. In these cases the stellar rotation may be the key. Unfortunately, the resolution of the AAOmega spectra does not allow to derive the  $v \sin i$  to corroborate this argument.

# Chapter 7

## Theory vs. Observation

In this chapter the results of the previous frequency analysis (Chap. 6 using the fundamental parameters (Chap. 5) are compared to theory of both  $g$  mode pulsation and  $p$  mode pulsation.

### 7.1 Instability strips

The hybrids reported from ground based observations were found in or close to the region in the HRD where the  $\delta$  Sct and the  $\gamma$  Dor IS overlap (e.g. HD 8801, HD 114839, BD +18 4914). It is natural to expect that for hybrids in this particular region the stellar pulsation behaves like  $\gamma$  Dor stars in the low-frequency regime and like  $\delta$  Sct stars in the high-frequency regime.

Figure 7.1 shows the location of the  $\gamma$  Dor stars compared to the position of the  $\delta$  Sct stars. The  $\gamma$  Dor stars concentrate at the red edge of the  $\delta$  Sct is and extend toward cooler temperatures even beyond the red edge of their IS. The  $\delta$  Sct stars are found as expected within their instability strip, with some outliers, of which the three hot cases are outstanding: CIDs 102620865, 102639464 and 102775698. These stars are classified by Sebastian et al. (2012) as A1V, A2V and A1V, which is in fair agreement with my independent parameter determination. The pulsation frequencies of these stars are typical for  $\delta$  Sct stars with dominant modes near 12, 20 and 15  $\text{d}^{-1}$ .

Fig. 7.2 shows that hybrid stars fill the whole  $\delta$  Sct instability strip and are even found beyond the red and the blue borders, like the  $\delta$  Sct stars. This finding is in good agreement with Uytterhoeven & WG#10 (2011), who analysed a sample from *Kepler* data. Thus, there is no distinct instability domain for hybrid stars, which would separate them from the  $\delta$  Sct stars. Like in the case of the  $\delta$  Sct stars one hot hybrid and two hybrid candidates are outstanding: CID 102649843 (A1V by Sebastian et al. 2012). Of the hybrid candidates CIDs 102677996 and 102792697 show  $\delta$  Sct and  $\gamma$  Dor frequencies but with amplitudes below 200 ppm and 250 ppm, respectively. Hence, background

**Figure 7.1:**  $T_{\text{eff}} - \log g$  diagram for pure  $\delta$  Sct and  $\gamma$  Dor. The green filled circles mark the  $\gamma$  Dor stars, the candidate  $\gamma$  Dor stars are displayed by open symbols and the  $\delta$  Sct stars are represented by red asterisks. The instability domains of both  $\gamma$  Dor and  $\delta$  Sct are shown by the dashed violet and dash dotted black lines, respectively. The borders of the  $\delta$  Sct IS are taken from Pamyatnykh (2000) and that for the  $\gamma$  Dor IS are taken from Dupret et al. (2004).

$\delta$  Sct stars or background hybrids are likely. These two candidates were classified as B9.5III and B9V Sebastian et al. (2012), respectively, which confirms again, that my parameter determination yielded acceptable results.

The natural assumption that hybrid stars are to be found in the region in the HRD, where the  $\delta$  Sct and the  $\gamma$  Dor IS overlap, is proven wrong according to these two figures.

Since driving of  $g$  modes of  $\gamma$  Dor stars is explained as a convective flux blocking mechanism (see Chap.7), the treatment of convection in the models becomes crucial. The location of the transition region, where the pulsation periods are of the same order as the thermal relaxation time, is of importance. For  $\gamma$  Dor stars, this transition region is near the bottom of the convective envelope, which results in driving of  $g$  modes (Dupret et al. 2007).  $\gamma$  Dor stars are cooler than  $\delta$  Sct and cooler than hybrids, as can be easily seen in Fig. 7.1. The convective flux blocking mechanism, however, does not work in hotter stars, thus, the identification of  $g$  modes for at least the hotter hybrid stars is questionable. On the other hand, the frequency analysis described in Chap. 6 was done carefully and ruled out confusion with combination frequencies, the orbit frequency (and its harmonics), eclipsing binaries, and known instrumental artefacts.

**Figure 7.2:** Same as Fig. 7.1 but for hybrids (filled triangles) and hybrid candidates (open triangles).

The outer convection zones of stars at  $T_{\text{eff}} \geq 7500$  K (hotter than the blue border of the  $\gamma$  Dor IS) near the ZAMS are shallow and should therefore play no significant role in the energy transport. Thus,  $g$  modes are expected to be stable (i.e., no pulsation) for such stars because of the lack of driving. On the other hand,  $g$  modes are observed in slowly pulsating B-stars (SPB stars). The modes of these stars are driven by the  $\kappa$  mechanism acting in the Fe-ionisation zone (Cox et al. 1992). Studies of the  $\kappa$  mechanism of F-type stars have shown that this mechanism cannot account for driving  $g$  modes of  $\gamma$  Dor stars (e.g. Gautschy & Loeffler 1996; Pamyatnykh 2000). Very recently, Shiode et al. (2012) investigated stochastically excited  $g$  modes for stars in the mass domain from 2 to  $30 M_{\odot}$ , which may explain hybrids hotter than the blue border of the  $\gamma$  Dor IS, but at this stage it is too early to draw firm conclusions.

The conjecture that there are practically no pure  $\delta$  Sct or  $\gamma$  Dor stars presented in the first *Kepler* publication by Grigahcène et al. (2010) is not confirmed by the CoRoT data of this thesis. I emphasise that in fact all of the presented  $\gamma$  Dor do not show evidence of  $p$  modes. The same is true for the  $\delta$  Sct stars, analogously. The slightly lower noise of the *Kepler* data does not explain the difference.

A strong case for a pure  $\gamma$  Dor star is HD 49434. The light curve of this Seismo target has a noise level of only 2 ppm in the Fourier domain and there are no frequencies near the expected fundamental mode or higher, that would indicate  $p$  mode pulsation. In this case the highest frequency is at  $12.03 \text{ d}^{-1}$  with an amplitude of  $\approx 30$  ppm, which is a mode of rather high spherical de-

gree between 6 and 8 according to the mode identification of Uytterhoeven et al. (2008). Hence, the identification as p mode has no solid basis and this star may be a fast rotating  $\gamma$  Dor.

## 7.2 Period – Temperature Relation

Figure 7.3 reveals a period – temperature relation for the program  $\gamma$  Dor stars, but no clear relation for hybrids. Generally, the cooler  $\gamma$  Dor stars have longer pulsation periods than the hotter stars. I considered here only the period with the highest amplitude for each star and for the hybrids combination modes were excluded.  $\gamma$  Dor stars discovered from the ground (listed by Henry et al. 2011) show a similar but not as tightly defined  $\log P - T_{\text{eff}}$  relation. For these stars a potential period - luminosity (in this case  $M_v$ ) relation was examined but no correlation was found (see Fig. 7.4). Instead of the luminosity, the absolute magnitude was chosen since it can be directly derived from the Hipparcos parallaxes.

Figure 7.5 shows  $T_{\text{eff}}$  vs.  $\log P$ , where the symbol sizes correspond to the square root of the amplitudes expressed in millimagnitudes. While the hybrids (filled triangles) scatter, the  $\gamma$  Dor stars (open symbols) show a correlation, as already depicted in Fig. 7.3. The upward pointing triangles mark the strongest  $g$  mode of the hybrids, while the downward pointing triangles display the strongest  $p$  modes of these stars. The open squares represent pure  $\delta$  Sct stars and linear fits to the  $\gamma$  Dor and  $\delta$  Sct stars are indicated by dashed lines. The 95% confidence intervals are displayed by the dash dotted lines. The hatched diamonds represent hybrids listed in Table 7.1.

The  $\gamma$  Dor stars cluster at  $\log T_{\text{eff}} = 3.85$  while the hybrids scatter in the  $g$  mode regime and do not show a  $T_{\text{eff}} - \log P$  relation. In the  $p$  mode regime the situation is similar: the pure  $\delta$  Sct stars also follow such a relation, but the hybrids do not at all. The hybrid stars have smaller  $g$  mode amplitudes than pure  $\gamma$  Dor stars, while their  $p$  mode amplitudes are comparable to that of the  $\delta$  Sct stars. Generally the  $g$  mode amplitudes of hybrids are lower than their  $p$  mode amplitudes. The amplitudes of  $\gamma$  Dor and  $\delta$  Sct stars are highest near  $\log T = 3.85$ , which is discussed later. The number of the hybrids from my analysis or from literature (Tab. 7.1) with reliable temperatures is too low to safely draw conclusions.

The  $\delta$  Sct stars show a very similar correlation of their temperatures vs. their strongest pulsation mode. The frequency of the radial fundamental mode and the first overtone show only a slight dependence on the effective temperature, but with increasing temperature higher radial orders are excited. More evolved  $\delta$  Sct stars tend to be cooler and have larger amplitudes, while the hotter  $\delta$  Sct stars have modes of higher radial orders excited. For a determination of the blue border of the  $\delta$  Sct instability strip I refer to Pamyatnykh

**Figure 7.3:** Effective temperature vs.  $\log P$  for hybrids (triangles),  $\gamma$  Dor stars (filled squares) and  $\gamma$  Dor stars from ground-based observations (violet dots). The data of the latter were taken from Henry et al. (2011).

**Figure 7.4:** Logarithm of the period versus absolute magnitude of 84  $\gamma$  Dor stars from ground based observations. The data are taken from Tab. 8 in Henry et al. (2011).

**Figure 7.5:** Log  $T_{\text{eff}}$  – log  $P$  diagram of the mean periods of  $\gamma$  Dor (open circles) compared to hybrids (triangles) and  $\delta$  Sct stars (open squares). The black filled diamonds represent the hybrids listed in Table 7.1 and the blue ring marks HD 49434. The mean period for each star is the average of the three  $g$  or  $p$  modes with highest amplitudes. The magenta dashed lines indicate linear regressions for the two samples, the dash dotted lines indicate the corresponding 95% confidence intervals.

(2000). The period – luminosity relation for HADS is known for a long time. A recent article on the period – luminosity relations of  $\delta$  Sct SX Phe and RR Lyrae stars can be found in McNamara (2011).

The linear regressions for  $\gamma$  Dor stars and for  $\delta$  Sct stars are given in Eq. 7.1 and 7.2.

$$\gamma \text{ Dor : } \log(P) = -11.56 * \log(T) + 44.23526, \quad (7.1)$$

and

$$\delta \text{ Sct : } \log(P) = -8.6723 * \log(T) + 32.327, \quad (7.2)$$

respectively, where P denotes the period in days of the strongest oscillation mode and T is the effective temperature in Kelvin.

Like in the case for g modes, the hybrids do not fit as nicely in this picture as the pure  $\delta$  Sct stars for p modes. There is generally more scatter than it is the case for pure  $\delta$  Sct. The hybrids listed in Table 7.1 are overplotted for comparison. The star HD 49434 is marked by a ring in Fig. 7.5, the hybrid status of which is disputed because of ambiguous p mode identifications.

Hotter stars generally show higher frequencies, which can be explained for pulsation driven by the  $\kappa$  mechanism ( $\delta$  Sct stars) in the following way: The opacity bump is located closer to the surface the hotter the star. Hence, the thermal relaxation time is shorter in this opacity bump and therefore excites modes of shorter periods. In the case of  $\gamma$  Dor stars the base of the convective envelope closer to the surface the hotter the star than in cooler stars. Again, the thermal relaxation time is shorter there which leads to shorter periods (Dupret, private communication).

**Figure 7.6:** Log  $P$  –  $T_{\text{eff}}$  diagram for the  $g$  modes of  $\gamma$  Dor compared to hybrid stars. The symbol sizes correspond to the amplitudes.

The temperature – period relation for hybrids is absent in contrast to the pure  $\delta$  Sct and  $\gamma$  Dor stars. Most of the hybrid stars possess higher p-mode amplitudes compared to their  $g$  mode amplitudes. Fig. 7.5 suggests that hybrid stars form a separate group of pulsating stars rather than being a simple combination of  $\delta$  Sct and  $\gamma$  Dor stars. As a counter argument, the physical properties of the stars under consideration ( $\delta$  Sct, hybrids,  $\gamma$  Dor) are not much different except for the convective envelope.

Fig. 7.6 shows the sample of the  $\gamma$  Dor and hybrid stars in more detail. As already discussed in Chap. 6 three types of  $\gamma$  Dor stars were introduced. The  $\gamma$  Dor stars of Type 3 are in total 22 stars and are at the cool, long period tail of the  $\gamma$  Dor stars in the  $\log T$  -  $\log P$  plane. The type 2 stars are characterised by a scatter of frequencies over the  $\gamma$  Dor frequency regime without distinctive clustering. Pulsation modes perturbed by fast rotation would explain such frequency patterns, as the rotational splitting of the modes becomes large. Only three such cases were detected without doubt, which makes them rather rare cases among the  $\gamma$  Dor stars. HD 49434 represents such a case (Chapellier et al. 2011). The sample of the hybrid stars was divided into two subgroups where the  $g$  or  $p$  modes are dominant, respectively. For neither subgroup any correlation with  $T_{\text{eff}}$  is evident.

## 7.3 $g$ modes

### 7.3.1 Observations Compared to Theoretical Frequencies

A. Miglio, J. Montalbán and collaborators calculated theoretical frequencies (private communication) of  $g$  modes for a grid of models. They used the stellar evolution code CLES (Code Liégeois d'Evolution Stellaire) for their models and the oscillation code LOSC (Liège Oscillation Code, Scuflaire et al. 2008a,b) to calculate the frequencies. The model grid covers 1.2 to 1.9  $M_{\odot}$  models in steps of 0.1  $M_{\odot}$  of two metallicities ( $Z = 0.01$  and  $Z = 0.02$ ) and three different mixing length parameters ( $\alpha_{\text{MLT}} = 1.4, 1.7$  and 2.0). Rotation was not taken into account.

The model frequencies are illustrated in Fig. 7.7. The modes of different  $\ell$  are vertically shifted by a small amount in mass for better visibility. The  $\ell = 3$  and 4 modes are not complete and their calculation was done to explore the instability domain rather than to give the full spectrum of those modes. The masses of models with excited modes depend on the metallicity, which is evident from comparison between the left and the right panels. For instance, with same mixing length parameter  $\alpha_{\text{MLT}} = 2.0$  the pulsating models range from 1.5 to 1.9  $M_{\odot}$  for  $Z = 0.02$ , while for  $Z = 0.01$  the masses of pulsating models range only from 1.3 to 1.5  $M_{\odot}$ . Changing the mixing length parameter from  $\alpha_{\text{MLT}} = 2.0$  to 1.4 the masses of the pulsating models decline.

Figure 7.8 shows the effect of changing the metallicity (left panel vs. right panel) and  $\alpha_{\text{MLT}}$  (symbols) on the position of the theoretical instability strip for the models. The IS shifts towards cooler effective temperatures and becomes narrower for metal-poor models. The theoretical IS for  $\gamma$  Dor stars was already derived by Dupret et al. (2004) based on the same input physics as the models used in this thesis. The position of unstable model frequencies compared to the observed ones is shown in Fig. 7.9 and 7.10 for  $\ell = 1$  modes and Fig. 7.11 and 7.12 for  $\ell = 2$  modes. The left panels of both figures compare the range of excited modes calculated with  $Z = 0.02$ , while the right panels those of to  $Z = 0.01$ .

The  $\gamma$  Dor stars cluster at  $\log T_{\text{eff}} = 3.85$  and show a steep gradient in their periods with  $\log T_{\text{eff}}$ , while the hybrid and candidate stars scatter and do not show any correlation with  $T_{\text{eff}}$ . The amplitudes of the  $\gamma$  Dor stars are also higher than those of the hybrids. Hence, the  $g$  modes of  $\gamma$  Dor and hybrid stars behave differently. The comparison of the periods of the pure  $\gamma$  Dor stars to the model frequencies shows a good agreement for  $Z = 0.02$  and  $\ell = 1$  and 2. For  $Z = 0.01$  the range in log period is narrower, but fit to the observation as well. The agreement of the theoretical frequencies for  $\alpha_{\text{MLT}} = 1.7$  and 2.0 is well, while it is poor for  $\alpha_{\text{MLT}} = 1.4$ .

In contrast, the  $g$  modes of hybrids and their candidates do not fit at all in this picture. This poses problems to the definition of hybrids: if these stars are

**Figure 7.7:** Frequency vs. mass of the models. Each dot represents one mode, the colours are as follows: black:  $\ell = 1$ , red:  $\ell = 2$ , green:  $\ell = 3$ , blue:  $\ell = 4$ , respectively. The  $\ell \neq 1$  are shifted in the vertical direction for better visibility. From top to bottom the panels show the effect of changing  $\alpha_{\text{MLT}}$ , and from right to left the effect of the metallicity.

**Figure 7.8:**  $\gamma$  Dor models with unstable modes. In the left panel models are shown for  $Z = 0.02$ , and  $Z = 0.01$  right, respectively.

**Figure 7.9:**  $\log T_{\text{eff}}$  vs.  $\log$  Period for  $\gamma$  Dor (open green circles) and  $\gamma$  Dor candidates (open violet circles). The periods displayed are the averages of the three modes of highest amplitudes. The area enclosed by the lines marks the positions of unstable theoretical frequencies of  $\ell = 1$  for three different  $\alpha_{\text{MLT}} = 2.0$  (solid line), 1.7 (dashed line) and 1.4 (dash dotted line). Left panel: Metallicity  $Z = 0.02$ , right panel:  $Z = 0.01$ .

**Figure 7.10:** Same as Fig. 7.9, but for hybrids (hatched upward triangles) and respective candidates (open downward triangles).

**Figure 7.11:** Same as Fig. 7.9, but for  $\ell = 2$  modes.

**Figure 7.12:** Same as Fig. 7.10, but for  $\ell = 2$  modes.

required to pulsate in the  $g$  mode regime as  $\gamma$  Dor and in the  $p$  mode regime as  $\delta$  Sct then they do not fulfil a strict definition of hybrids. On the other hand, I excluded combination frequencies and single frequencies in the  $\gamma$  Dor regime, to avoid confusion with rotation or other effects. Likewise, eclipsing binaries were excluded and the low frequencies of instrumental artefacts are below the  $\gamma$  Dor frequency range. Thus, these frequencies can only be explained either by  $g$  modes or by rotation variation caused by a complexly spotted surface, which is rather unlikely.

The problem of rotation should be discussed briefly. The rotation period of an observed  $\gamma$  Dor star is a priori unknown;  $v \sin i$ , if available, gives an upper limit of the true rotation period. Observations of  $\gamma$  Dor stars show that they can be fast, moderate or slow rotators. Moreover, the rotation period may be of the order of the pulsation periods, which causes asymmetric rotational splittings of the  $g$  modes. The perturbative approach widely used to calculate such splittings is valid for slow rotation only. The centrifugal force distorts the star and at high rotation rates the spherical harmonic approximation can no longer be applied because the star deviates from spherical symmetry. Unfortunately, the spectral resolution of the AAOmega spectra do not allow a determination of  $v \sin i$ .

The importance of convection may be indicated by the pulsation amplitudes: both pure  $\gamma$  Dor and  $\delta$  Sct stars show their highest amplitudes at a temperature of  $\approx 7000$  K. Warner et al. (2003) published a theoretical instability strip for  $\gamma$  Dor stars, where they also showed the growth rates for  $g$  modes versus  $T_{\text{eff}}$  and luminosity (Fig. 7.13). They found the largest growth rates for  $g$  modes close to  $T_{\text{eff}} = 7000$  K. The growth rates of  $p$  modes of  $\delta$  Sct stars are as well in agreement (see Chap. 7, Fig. 7.16). I note that from linear theory it is not possible to calculate amplitudes, nevertheless my finding correlates well with the trend in the growth rates. On the other hand, it is obvious that amplitudes carry important information but due to the lack of theoretical amplitudes this information cannot be exploited yet. Additionally, the fraction of constant stars has a minimum at this temperature (see Fig. A.1).

### 7.3.2 Period spacing

The first order asymptotic theory (Tassoul 1980) allows to compute the pulsation period for a given spherical degree  $\ell$  and radial order  $n$  as:

$$P_{n,\ell} = \Pi_0 \frac{2\pi^2(n + 1/2)}{\sqrt{\ell(\ell + 1)}}, \quad (7.3)$$

where

$$\Pi_0^{-1} = \int_{r_a}^{r_b} \frac{N}{r} dr, \quad (7.4)$$

FIG. 3.—Plot of growth rates of models in our calculated instability strip for  $\ell = 1$  in the  $T_{\text{eff}}-L$  plane. This is the lower bounding value of  $\ell$ , representing the most restrictive case. The log of the growth rate (AKE/KE per period) is shown on the  $z$ -axis.

**Figure 7.13:** Growth rates from Warner et al. (2003, Fig. 3 therein). Reproduced by permission of the AAS.

$N$  denotes the Brunt-Väisälä frequency and  $r_{a,b}$  are the inner and outer turning points, respectively. The period spacing  $\Delta P$  is then defined as

$$\Delta P = P_{n,\ell} - P_{n-1,\ell}. \quad (7.5)$$

$\Delta P$  denotes the period spacing which becomes equal for high values of  $n$ . The asymptotic approximation may be valid at least for young unevolved stars. Miglio et al. (2008) showed that the period spacings of  $g$  modes are not only sensitive to chemical gradients deep inside the star, moreover, they become periodic with the radial order  $n$  as the star evolves. During the evolution, more and more hydrogen is fused to helium in the core and therefore a chemical gradient emerges and gets steeper and steeper. From the observation of white dwarfs (e.g. ZZ Ceti stars) it is known that the period spacings of  $g$  modes in the asymptotic regime are sensitive to chemical gradients in the interiors of these stars (e.g. Brassard et al. 1992). Not only the chemical gradient but even more the rotation of the star causes deviations from a constant period spacings. In real data a strict period spacing could be found, if the star rotates slow enough and shows only modes of equal  $\ell$ . From an observational point of view it is impossible to disentangle these effects if the  $v \sin i$  and the inclination angle  $i$  are unknown. To safely detect the period spacings mode identification is vital. With space-based data many periods are detected with low amplitudes and therefore there is the chance of accidentally detecting constant period spacings of unrelated modes.

In this thesis, I tried to detect such period spacings, where I limited the search to constant spacings. Such spacings were found, but they were unexpectedly small if  $\ell = 1$  modes are considered (see Chap. 6, Table 6.2). If the period spacings were due to higher  $\ell$ , the spacing scales according to

$$\frac{\Delta P(\ell_i)}{\Delta P(\ell_j)} = \frac{\sqrt{\ell_j(\ell_j + 1)}}{\sqrt{\ell_i(\ell_i + 1)}}, \quad (7.6)$$

where  $\Delta P(\ell_i, j)$  denotes the period spacing for  $\ell = 1, 2, \dots, n$  modes.

Figure 7.14 shows the average period spacing expected from theory as a function of the effective temperature. The lines connect models of the same mass and thus reflect the evolution of these models. The average period spacing declines along the evolutionary track from core hydrogen abundance  $X_c = 0.7$  (ZAMS) to  $X_c = 0.0$  (TAMS). When considering models on the ZAMS of different masses the graph shows that the period spacings of higher mass models are larger than those of lower mass models. The extreme values of the average spacings for stars in the  $\gamma$  Dor domain range from  $\approx 3600$  s ( $= 0.0417$  d) for model including core overshooting ( $\alpha_{ov} = 0.2$ ) at  $\log T_{\text{eff}} = 3.88$  to  $\approx 2000$  s ( $= 0.023$  d) for evolved models without core overshooting and  $\log T_{\text{eff}} = 3.82$ . As the stars evolves, the deviations of individual spacings from the average period spacing become significant and therefore such cases are not detectable with my method, which allows only for deviations of the order of the period resolution of the data set.

Figure 7.15 shows the period spacings versus  $\log P$ . The y-axis is plotted logarithmically and the dashed lines indicate the average period spacings expected for  $\ell = 1$  to 3 modes. The period spacing correlates weakly with the main period, so that for shorter periods shorter period spacings are detected. The detected spacings are in general too short to account for consecutive  $\ell = 1$  modes or even  $\ell = 2$  modes. No firm detection of  $\ell = 1$  or 2 modes was achieved. The results for the individual stars are listed in Tab 6.2.

**Figure 7.14:** Theoretical period spacing as a function of  $\log T_{\text{eff}}$ . The red circles represent models without core overshooting, the blue crosses correspond to models calculated with core overshooting parameter  $\alpha_{ov} = 0.2$ . The period spacings shown are the average spacings for different evolutionary stages of the models.  $X_c = 0.7$  and  $X_c = 0$  indicate models on the ZAMS and TAMS, respectively. The models shown were calculated from  $2.5$  to  $1.4 M_{\odot}$  in  $0.1 M_{\odot}$  steps, which exceeds the  $\gamma$  Dor instability domain. Figure courtesy of A. Miglio.

**Figure 7.15:** Period spacings vs. main period. The dashed lines indicate average period spacings for  $\ell = 1$  to 3 modes.

## 7.4 $p$ modes

Since hybrid stars pulsate with  $p$  modes like the normal  $\delta$  Sct stars, the  $p$  mode pulsation of  $\delta$  Sct stars are discussed here. The  $\kappa$  mechanism acting in the He II ionisation zone is commonly accepted as driving mechanism of these  $p$  modes. I refer to the Introduction and the cited papers therein for exhaustive information on  $\delta$  Sct stars. From my sample, 90  $\delta$  Sct stars were identified for which the parameter determination was done accordingly.

To compare the observations with theory, A. Pamyatnykh and T. Zdravkov (private communication) calculated radial modes from  $n = 1$  to 10 and their growth rates for a grid of models, ranging from  $M = 1.5$  to  $2.4 M_{\odot}$ . For a comprehensive discussion of the theoretical aspects of  $\delta$  Sct stars and the detailed input physics I refer to Pamyatnykh (2000). Fig 7.16 shows the period of the radial mode with the highest growth rate compared to the observations of pure  $\delta$  Sct stars. The symbol size of the model periods correspond to their respective growth rate (upper panel). The symbol sizes of the observations correspond to the amplitude (middle panel) and to the luminosity, which is substituted by the inverse  $\log g$  (bottom panel). The area enclosed by the thick orange line shows the range of the main sequence models. The red border of the  $\delta$  Sct IS is indicated by a horizontal red line. Generally, the agreement of the models and the observations is excellent. The calculated growth rates are compatible with the observed amplitudes and the more evolved stars show larger amplitudes. Again, the range in temperature of the red border of the

$\delta$  Sct IS is indicated by the red line, as in Fig.7.17.

Figure 7.17 compares the period of the mode of maximum amplitude of the  $\delta$  Sct stars (left panel) to that of the hybrids (right panel). The period-temperature relation for  $\delta$  Sct stars is evident, while it is completely missing for hybrids. Contrary, their pulsation modes scatter and do not show any correlation with temperature. Thus, not only do the  $g$  modes of hybrids behave differently as the  $g$  modes of  $\gamma$  Dor stars, also the  $p$  modes behave differently from that of pure  $\delta$  Sct stars. Based on these parameters ( $\log P$  and  $\log T_{\text{eff}}$ ), there is a difference of the pulsation behaviour of hybrids (the mix) to the pure  $g$ - or  $p$ -mode pulsators. Do the hybrids comprise a different class of pulsating stars? The amplitudes of the  $\delta$  Sct stars in the  $T_{\text{eff}}$  regime of  $\approx 7000$  K reveals that the maximum amplitudes are in this regime as it is the case for the  $\gamma$  Dor stars. These  $\delta$  Sct stars are near the TAMS and are therefore more luminous than stars close to the ZAMS. The  $p$  mode amplitudes of the hybrids, however, do not show a pronounced maximum in  $T_{\text{eff}}$ .

**Figure 7.16:**  $\log T_{\text{eff}}$  vs.  $\log P$  of  $\delta$  Sct models compared to 75 observed  $\delta$  Sct stars. Top panel: The symbols represent the  $\delta$  Sct models with masses ranging from 1.6 to  $2.2 M_{\odot}$ . The mode of the maximum growth rate is shown for each model and the symbol sizes corresponds to this maximum growth rate. For better visibility, only every tenth model is shown. The area enclosed by the full line shows the envelope of unstable radial modes of these models. Middle panel: Observed period of the p mode of maximum amplitude vs.  $T_{\text{eff}}$ . The symbol size scales with the amplitude. Bottom panel: the symbol size scales with  $\log g$ , where larger symbols represent evolved stars and the smallest symbols correspond to ZAMS stars. The horizontal red line displays the range of the red border of the  $\delta$  Sct instability strip.

**Figure 7.17:** Comparison between the period of maximum amplitude of pure  $\delta$  Sct stars (left panel, black squares) and hybrid stars (right panel, red triangles). The red straight line, denoted by  $\Delta \text{ IS red}$ , indicates the temperature range of red border of the  $\delta$  Sct instability domain from ZAMS to evolved stars.

# Chapter 8

## Conclusions and Outlook

I have shown that  $\delta$  Sct -  $\gamma$  Dor hybrid stars do exist as a distinct group by means of thorough frequency analysis of about 250 stars. The frequency lists of each of these stars are enclosed in the Appendix and ready to use for the scientific community. Contrary to the *Kepler*-team (Grigahcène et al. 2010), I have shown that there are indeed pure  $\gamma$  Dor and  $\delta$  Sct stars, while the number of true hybrids is considerably lower in my sample. This sample included the LRA01 Exo data of the CoRoT mission and 5 individual stars of which 4 are hybrids and one is a  $\gamma$  Dor star. Of course the different noise levels of the two space mission's data sets has to be considered, however my detection limit of the CoRoT LRA01 data is 20 ppm for stars of about 12 mag and 100 ppm for 15 mag stars, which is sufficient for a well established conclusion.

One major finding is, that there is no specific instability strip for hybrid stars. Our finding is in good agreement with that of Uytterhoeven & WG#10 (2011) for *Kepler*, which confirms the fact that hybrid stars are found across the  $\delta$  Sct instability strip and are not confined to the overlapping region of the  $\delta$  Sct and  $\gamma$  Dor instability strip. The fundamental parameters determined in this thesis are derived from homogeneous classification spectra, whereas the temperatures of Uytterhoeven & WG#10 (2011) are derived from various sources. The *Kepler* light curves are available in long cadence (LC) or short cadence (SC) with Nyquist frequencies of  $\approx 24 \text{ d}^{-1}$  and  $\approx 730 \text{ d}^{-1}$ , respectively. The low Nyquist frequency of the LC data are problematic for detecting  $\delta$  Sct stars or hybrids, because their pulsation periods can be higher and reflections at the Nyquist frequency could lead to spurious identifications. In contrast, the CoRoT Exo data do not suffer from such spurious detections, because their Nyquist frequency is high enough to avoid this kind of problems.

The  $g$  modes of hybrids do not behave like those of the pure  $\gamma$  Dor stars which was found by a comparison of model frequencies to observed data (Chap: 7). Their periods do not correlate with  $T_{\text{eff}}$  as it is the case for  $\gamma$  Dor stars and their amplitudes are generally lower than that of the pure  $\gamma$  Dor stars. The effective temperatures of hybrid stars are hotter than the blue edge of the

$\gamma$  Dor IS, which means shallow sub-surface convection zones and therefore the conditions for driving g modes are not fulfilled. The amplitudes of their g modes are generally lower than that of pure  $\gamma$  Dor stars. The very recent theory of stochastically driven g modes of Shiode et al. (2012) could deliver an explanation, but it is speculation at this stage.

Even the p modes behave on average differently to that of the pure  $\delta$  Sct stars, which is a surprising result. A possible solution for this problem may be found in the excitation of low-order g modes, which are detected in  $\delta$  Sct stars (eg. Breger et al. 2005). In this case the low-order p modes are the dominant frequencies because I limited the comparisons in Chap. 7 to the three modes with highest amplitudes. This finding may point to unknown physical processes in the  $\delta$  Sct or hybrid stars. It could have an impact on the role of chemical mixing inside the stars and therefore on the opacities. The  $\kappa$  mechanism acts in the HeII ionisation zone and is sensitive to the opacities.

The  $\gamma$  Dor stars basically follow the instability strip which was determined from ground-based observations (Handler & Shobbrook 2002) and theoretical predictions (Warner et al. 2003; Dupret et al. 2004). But there are deviations: 1) the  $\gamma$  Dor instability strip determined in this work extends to cooler stars; 2) stars hotter than  $T_{\text{eff}} = 7500$  K were found showing low-amplitude variability within the  $\gamma$  Dor frequency regime, which may be interpreted as g mode pulsation. For such stars, the convective flux blocking mechanism can no longer explain the driving of such modes. Nevertheless, the observational evidence is striking. Again, the theory of stochastically excited g modes could provide a clue. However, at this stage it is too early to draw conclusions and this theory needs to be investigated in more detail, which could be done in a follow-up project.

The comparison of the g modes of  $\gamma$  Dor stars to model frequencies (see Chap. 7) showed a good agreement for  $\alpha_{\text{MLT}} = 2.0$  and 1.7, while for 1.4 the agreement is poor. Based on the comparison of  $T_{\text{eff}}$  vs. period between theoretical and observed frequencies, there is evidence that at least some of the  $\gamma$  Dor stars pulsate with  $\ell = 2$  modes, which have higher frequencies than  $\ell = 1$  modes. I also performed the search for regular period spacings among the  $\gamma$  Dor stars. For this purpose I modified the Comb Response Function (Kjeldsen et al. 1995) to accommodate the needs for g modes. I also used the routine of SigSpec (Reegen 2007), which calculates the significance spectrum and modified it in order to calculate the significances for a regular grid of periods instead of frequency. This search led to surprisingly low period spacings, where at this point it is not clear whether simply high  $\ell$  are excited or these spacings have another physical meaning. I consider it imperative to have for at least a statistically significant spectroscopic mode identification to prove or reject the hypothesis of consecutive modes of equal  $\ell$ .

$\gamma$  Dor stars show maximum g-mode amplitudes at  $T_{\text{eff}} \approx 7000$  K, and so do  $\delta$  Sct stars. This temperature regime is approximately the range, where

the growth rates of  $g$  modes calculated by Warner et al. (2003) are at maximum. In this same  $T_{\text{eff}}$  regime the model frequencies of Pamyatnikh (private communication) exhibit their maximum growth rates, when main sequence models are considered. However, from linear theory no amplitudes can be calculated, which limits the significance of this finding.

Detailed abundance analyses of  $\delta$  Sct -  $\gamma$  Dor hybrid stars are still lacking. I contributed two such analyses for BD +18 4914 and HD 114839 with the goal of investigating chemical peculiarities among hybrid pulsators. Peculiar chemical abundances may indicate diffusion processes that could influence the pulsation behaviour of  $\delta$  Sct or hybrid stars. Since the first reported hybrid is an Am star, (Henry & Fekel 2005) and HD 114839 and BD +18 4914 (King et al. 2006; Rowe et al. 2006b) were suspected Am stars, high resolution spectra for a detailed abundance analysis were acquired. The abundance analysis resulted in the finding that HD 114839 is not an Am star, while BD +18 4914 is. The conclusion from this abundance analysis is that hybrid stars are not necessarily Am stars. The research for common spectral features of hybrids gave a negative result. There is no common feature among the spectra of the hybrid stars that distinguishes them from other stars, however statistics is still poor.

To derive the fundamental parameters an IDL program was developed which compares synthetic to observed spectra and selecting the best fitting synthesis for the representative parameters. This IDL routine is not limited to my spectra, but can be modified to accommodate for the needs of other purposes. The easiest example is to use a different grid of synthetic spectra which uses more sophisticated model atmospheres than ATLAS9 or different metal abundances. It may be also adapted easily for other kinds of spectroscopy.

The total amount of identified  $\gamma$  Dor stars in the CoRoT LRA01 Exo field is 132 including candidates and cases with bad spectra. The total number of pure  $\delta$  Sct stars is 90 (also including candidates and bad spectra), and the total of hybrids is 111 including 57 unclear cases. This high number of remaining candidates shows the difficulty to firmly classify a given hybrid candidate as a firm detection because of a few remaining low-amplitude frequencies. Due to fringing problems with some fibres of the AAOmega spectrograph some stars were rejected because of uncertain parameter determination. I omitted such data in the comparison to theoretical frequencies and for investigating the  $T_{\text{eff}}$  – Period relations but they were retained for the frequency analysis.

In total 333 stars were found pulsating within the  $\delta$  Sct and  $\gamma$  Dor IS. Of these stars 40% were identified as  $\gamma$  Dor stars or candidates, 27% as pure  $\delta$  Sct stars, 17% are bona fide hybrids, where 23 of 58 show dominant  $p$  mode pulsation, 16 showing dominant  $g$  mode pulsation and 18 show no preferred class of pulsation (i.e.  $p$  or  $g$  modes). The considerably large portion of 16% are hybrid candidates, of which two thirds showing dominant  $\delta$  Sct pulsation, which means that the total number of true  $\delta$  Sct stars is somewhat higher.

Two of the stars in my sample are eclipsing binaries, listed in the catalogue of Carone et al. (2012). I found one  $\gamma$  Dor star (CID 102726709), which shows a dip in the phase diagram, that could indicate a grazing eclipse by a binary component with an orbit period of about 1.28 days. This star definitely show pulsation and is no misclassification of an eclipsing binary. Otherwise it would have been rejected.

Due to their position in the HRD the stellar structure of hybrid stars can be expected to be the same as for  $\delta$  Sct stars. Even though the  $\log g$  can only be determined with large errors from the AAOmega spectra, it still allows to distinguish giants from main sequence stars. The hybrids observed by MOST and CoRoT allow for a much better determination of their luminosities. Furthermore, the analysis of the high resolution spectra of HD 114839 and BD +18 4914 have shown that hybrid stars fit well in the  $\delta$  Sct IS and are therefore not evolved stars or even subdwarfs.

I restricted the volume of the examination of a large sample to the CoRoT LRA01 because of time limitation. The total amount of light curves observed by CoRoT meanwhile exceeds 100 000. More work on the definition of the  $\delta$  Sct IS is done by A. Kaiser (PhD thesis in preparation), whose thesis comprises data of about 14000 stars including stars of my sample.

The *Kepler* data benefit not only from the larger aperture and the location in the Lagrange point L2, which is 1.5 million km away from earth, but even more important from the long time base. So far more than 150,000 stars were continuously monitored for about 3.5 years. Such a long time base helps to overcome the problem of combinations and amplitude modulations, because of the small frequency error. On the other hand, only a few targets can be observed in short cadence mode. The long cadence data are problematic for  $\delta$  Sct stars, because their Nyquist frequency is well within the range of typical  $\delta$  Sct pulsation.

The importance of multi-object classification spectroscopy for a large number of stars is being recognised. High resolution spectroscopy of a large sample of stars are currently planned or already carried out at the time of writing. The APOGEE (APO Galaxy Evolution Experiment) project should be mentioned here. It will take medium resolution ( $R \approx 20000$ ) spectra of about 100000 stars, mainly red giants in the infrared (1.59 - 1.69  $\mu\text{m}$ ). For such a large number of spectra automated routines are of particular importance. The automated routine developed for the purpose of the thesis can be applied for spectra too, it is not not limited to AAOmega spectra.

We are at the beginning of large-sample stellar statistics based on highly accurate space-based data of both the fundamental parameters and the light curves. The launch of the European Space Agency's GAIA (Global Astrometric Interferometer for Astrophysics) spacecraft is planned for 2013 and the final data release is planned for 2020. It is an astrometric mission that will provide accurate parallaxes of a billion of stars in our milky way.

The accurate distances will allow to directly derive stellar luminosities and place the star in the HRD without the problem of the poor accuracy in  $\log g$ . The parallax errors are expected to be small that allows to reduce the error box of the observations, which is an important prerequisite for asteroseismology, since the models that fit the observational error box will be significantly constrained.

On one hand, the pulsation of  $\gamma$  Dor stars is in good agreement with theory, but on the other hand the g modes of the hybrids are generally a contradiction to the present theory. The high quality light curves of space instruments and their long time span are however only a snapshot of the main sequence lifetime of a star. During the investigation of the CoRoT LRA01 sample, non-variable stars were detected within the  $\delta$  Sct IS see Appendix A. These stars contradict the pulsation theory completely. On the other hand, such stars might undergo long time cycles of pulsation and quiescence.

# **Appendix A**

## **Byproducts**

In this appendix I discuss other stars encountered during the investigation that were not subject of the thesis.

## A.1 Nonvariable Stars

Not only pulsating stars are of interest, but also the distribution of constant stars within the  $\delta$  Sct IS can be explored. The AAOmega spectra were used to find stars within the  $T_{\text{eff}}$  range of 11000 to 6000 K. The CoRoT light curves of these stars were investigated for pulsation. Among  $\approx 1000$  stars, 424 did not show variability apart from instrumental artefacts in the light curves. Figure A.1 shows the fraction of constant stars and the classes of variables across the IS. Out of  $\approx 1000$  stars 424 are constant to a detection limit of  $\approx 20$  ppm for 12 mag stars, to about  $\approx 100$  ppm for the faintest stars. Stars were assigned to the class unclear if the light curves retained artefacts that may conceal intrinsic variability. Stars like Cepheids or stars with longer periods than 10 days are assigned to the class LPV, stars with a single frequency or strictly repeating patterns were assigned to the class rotation variability (Rot.var.). The fraction of constant stars within the IS is lowest at  $T_{\text{eff}}$  between 6900 and 7500 K, which is 14% at  $T_{\text{eff}} = 6900$  and 7200 K.

The distribution of constant stars is also investigated in this thesis, where constant means constant to the detection limit of about 20 ppm for brighter stars and 100 ppm for the faintest stars. The relative number of constant stars as a function of their temperature shows a local minimum at  $T_{\text{eff}} \approx 7000$  K. Our investigation has shown that 14% of the stars within this temperature regime are constant, or their amplitudes are too low to be detected with CoRoT. The fraction of constant stars in this  $T_{\text{eff}}$  regime may even be lower when *Kepler* data are investigated. It is unknown by now why a star within the  $\delta$  Sct or  $\gamma$  Dor instability regime is constant while others are pulsating. Strong global magnetic fields could serve as an explanation, because they can suppress pulsation. Thus, high resolution spectra and polarimetry of such constant stars may resolve this puzzle.

Not only the percentage of constant stars is lowest near  $T_{\text{eff}} \approx 7000$  K, but also pulsating stars show the highest amplitudes in this temperature regime. This may explain why hybrid stars were found by ground based observations in the overlapping region of the  $\delta$  Sct and  $\gamma$  Dor instability strips, which is located as well in this  $T_{\text{eff}}$  region.

**Figure A.1:** Cumulative histogram of constant and variable stars. The variables are listed in the legend and to be read from top down. The colored bars on top represent the fraction of constant stars within a  $T_{\text{eff}}$  bin.

## A.2 Variables beyond the IS

This thesis puts the focus on  $\gamma$  Dor and  $\delta$  Sct type variability. Thus, the determination of the fundamental parameters and the analysis of the light curves was optimised for those stars. There are many other types of variables detected by CoRoT, which were not analysed in this thesis. However, some cases are mentioned below.

The blue edge of the  $\delta$  Sct strip was derived by Pamyatnykh (2000). It shifts towards hotter temperatures with increasing radial overtone. Stars hotter than 8900 K on the ZAMS or 7600 K on the TAMS (Terminal Age Main Sequence) are not expected to show  $\delta$  Sct pulsation, since their growth rates are negative. However, such hot pulsating stars were found.

On the other hand, hot  $\gamma$  Dor stars with low amplitudes were also discovered. One case is outstanding: The star CID 102597681, which was discussed in Chap. 6. High resolution spectroscopy (Carone et al. 2012) revealed a SB3 system whose integrated light is dominated by an A-type star. Neither the AAOmega spectrum nor the image of the mask shows peculiarities. Other cases of hot  $\gamma$  Dor stars were found, but with considerably lower amplitudes. Since no high resolution spectra are available for these stars, cannot be exclude cases like CID 102597681.

Rather cool stars showing frequencies in the  $\gamma$  Dor regime are also found. Their Fourier spectra show closely separated peaks and their overtones (twice and three-times the main frequency), which is the signature of a nonsinusoidal

variation. An explanation may involve spots at different latitudes and differential surface rotation.

### **A.2.1 Maia-Candidates**

Stars located in between the blue edge of the  $\delta$  Sct and the SPB IS in the HRD are not supposed to pulsate. The Maia variables were introduced by Struve (1955). They are B7V-III to A2V-II stars and named after the first candidate star Maia in the Pleiades. Scholz et al. (1998) presented a list of 14 Maia candidates. They found light variations as well as RV variations for a few of them line profile variations that they attribute to nonradial pulsation. The periods they presented are in the range of g modes of SPB stars. Thus these stars might be cool SPB stars. A number of the reported Maia candidates are binaries, such as  $\alpha$  Draconis (Kallinger et al. 2004). Therefore tidal excitation may play a key role to explain the variability of these Maia candidates. In the CoRoT data such stars can easily be found. We note, that our synthetic spectra fitting routine gives large uncertainties for such stars, which are typically of the order of 10 to 20 %. A detailed analysis of these stars was beyond the scope of this thesis.
